CANDIDATE'S DECLARATION

I hereby certify that the work which is being presented in the thesis entitled **"STRUCTURE-PROPERTY RELATIONS IN HIGH MANGANESE-CHROMIUM-COPPER WHITE IRONS"** in fulfilment of the requirement for the award of the Degree of Doctor of Philosophy and submitted in the Department of Metallurgical Engineering of the University is an authentic record of my own work carried out during a period from October, 1987 to October, 1993 under the supervision of **Dr. A.K.Patwardhan.**

The matter presented in this thesis has not been submitted by me for the award of any other degree of this or any other University.

(CHETANYA PRAKASH SHARMA)

This is to certify that the above statement made by the candidate is correct to the best of my knowledge.

Date: Oct'16 , 1993

(Dr. A.K. PATWARDHAN) 16/10/93
Professor, Metallurgical Engg.
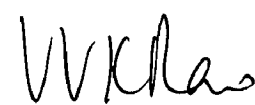

The Ph.D. Viva-Voce examination of Mr. CHETANYA PRAKASH SHARMA, Research Scholar, has been held on 9th February, 1994

Signature of
Supervisor 9/2/94

Signature of Head of
the Department 9/2/94

Signature of
External Examiner

WITH THE BLESSINGS
OF
OMNISCIENT, ALMIGHTY

DEDICATED
TO
MY GRAND PARENTS
LATE SHRI (PANDIT) M.L. SHARMA & LATE SMT. H.D. SHARMA

AND

MY PARENTS
SHRI B.S. SHARMA & LATE SMT. N.D. SHARMA

MRS USHA (WIFE), AVANTIKA (DAUGHTER) AND ANU AYAM (SON)

PREFACE

The thesis comprises a total of eight chapters. The first chapter introduces cast irons as materials of construction. It deals with important varities of gray cast irons such as Compacted graphite Silal, Nicrosilal, High Silicon irons and Ni-Resist irons. The second chapter deals with 'in depth' information on corrosion, wear, and heat resistant white irons. The usefullness of the Fe-Mn-Cr-Cu alloys, in resisting corrosion and wear, forms the basis of formulating the present problem highlighted in Chapter-III.

Chapter IV deals with the experimental techniques and procedures employed with major emphasis on the X-ray diffracto-metry, EPMA, DTA, corrosion testing, compression testing, and quantitative optical metallography.

Results and discussion have been divided into three chapters. Chapter V includes the effect of heat treating parameters on the hardness and microstructure characterized qualitatively as well as quantitatively. This has led to the development of a number of models and some new ideas encompassing 'quantitative characterization of 2nd phase particles' and 'homogeneity/heterogeneity' of the alloy(s)/system.

Chapter VI deals with the (i) structural investigations by X-ray diffractometry and EPM analysis to carry out a detailed phase analysis and for assessing the partitioning behaviour of Mn, Cr, Si, and Cu into the matrix, massive carbide, dispersed second phase(spherical & plate like) and the hitherto unobserved gray etching phase(formed on heat treating from 1000°C and (ii) study of the transformation behaviour of the alloys by DTA primarily to assess the suitability of selected microstructures for high temperature applications.

Chapter VII is devoted to an assessment of the deformation behaviour of selected microstructures in the as-cast and in the heat treated conditions by compression testing, electro-chemical characterization of selected microstructures by weight loss methods, and a study of the corroded specimens by scanning electron microscopy.

A salient feature of the present study has been the development of a number of mathematical models interrelating the

(i) heat treating parameters with the hardness,

(ii) microstructure (especially the effect of second phase corresponding MC & DC) with the corrosion rate,

(iii) hardness with the compression strength,

(iv) compressive strength with the corrosion behaviour,

(v) distribution of the massive & dispersed second phase with homogeneity/heterogeneity

(vi) size distribution of the dispersed second phase with coarsening

Based on the above findings, conclusions have been drawn with regard to the transformation behaviour of the alloys under various heat treating conditions and the suitability of different microstructures from the point of view of corrosion resistance, and mechanical properties finally leading to the optimization of microstructure for obtaining the aforesaid properties. They (conclusions) are enumerated in the chapter VIII.

The key features of the present investigation are (i) the development of corrosion resistant cast iron having corrosion resistance comparable to that obtained in the conventional Ni-Resist cast irons with an additional advantage of improved mechanical properties, (ii) defining a new parameter to represent the homogeneity/heterogeneity of the structure, (iii) development of several 'models' very useful for optimizing microstructure & for quantifying structure-property relations, and (iv) extensive use of computational techniques and the development of application software, of immense use for materials development/ characterization, for the IBM compatible PC-AT & PC-486 systems.

SYNOPSIS

[A] OBJECTIVE(S)

The present study essentially comprised a detailed investigation of certain newly designed Fe-Mn-Cr-Cu white irons, containing 10Mn-7Cr-3.7C and alloyed with 1.5, 3.0, and 5.0%Cu, in the air cooled condition. The investigation forms a part of an 'on-going' research programme, aimed at developing a new generation of 'corrosion resistant irons', to overcome the limitations of highly alloyed 'Ni' containing proprietary compositions called 'Ni-Resist' irons. The study comprised assessing the heat treatment response of the experimental alloys with a view to establish interrelation between structure and properties. Establishing the transformation characteristics, which formed the base of the study, was carried out by employing hardness measurements, optical and scanning metallography, quantitative metallography, X-ray diffractometry, electron probe micro analysis and differential thermal analysis.

Electrochemical characterization was carried out by the weight loss method. Compression testing proved useful in assessing the deformation behaviour. Computational techniques were extensively employed for data analysis using IBM compatible PC-XT and PC-486 systems.

[B] MAJOR FINDINGS AND MODELS DEVELOPED

Round specimens of the three alloys C1, C2, and C3 were aircooled from 800, 850, 900, 950, 1000 and 1050°C after holding for 2, 4, 6, 8 and 10 hours. The microstructure, which was influenced by the Cu content and heat treating schedule, comprised : (i) Austenite (A) + Martensite (M) + MC in the as-cast state and on heat treating up to 850°C, (ii) A + MC + dispersed second phase (DSPs) on heat treating up to 950°C, (iii) A + MC (mostly rounded/hexagonal) + some stray dispersed carbides (DCs) on heat treating up to 1000°C, and (iv) A + agglomerated MCs treating up to 1050°C.

Increasing the temperature and/or soaking period decreased the amount of massive carbides (MCs). This tendency was marked at >950°C. Carbides were mostly discontinuous on heat treating from 900°C and the 'rounding-off' tendency set in at 950°C.

Dispersed second phase (DSPs) formed on heat treating at 800°C and 850°C directly from austenite. They either had a needle shaped or a rounded morphology and coarsened with temperature and time, the tendency being marked at 900°C and 950°C. Coarsening has been represented by a newly evolved parameter called the 'coarsening index'(CI). The dispersed carbides dissolved on heat treating from 1000°C.

C1:10Mn-7Cr-1.5Cu; C2:10Mn - 7Cr - 3.0Cu; C3:10Mn - 7Cr - 5.0Cu

Hardness measurements provided a reliable measure of the mechanical properties of the transformation product(s). The relationship between hardness, temperature & time is of the form:

$$H = K1\ e^{K2/T} + (K3 + K4.T).t$$

where, H = hardness (VHN$_{30}$); T = temperature (°K); t = time (seconds); and K1, K2, K3 and K4 are constants and are different for different alloys.

This model has been shown to be valid and physically consistent with the structural changes with the first term modelling the matrix transformations and the second term the 'carbide' transformations. 3D plots between hardness - temperature - time and the 'iso-hardness' plots gave a useful insight into the hardness sustaining ability of the alloys.

It has been demonstrated that the transformation behaviour, arrived at on the basis of 30 experiments can be equally accurately predicted based on merely 4 or 6 experimental data points by 'simulating' the 'modelled' transformation behaviour. The new idea put forth could greatly help in minimizing arduous experimentation and needs further exploring.

The variation in volume fraction of MCs and DCs for a given heat treatment has been utilized to evolve a new parameter called the homogeneity/heterogeneity index of the alloy/alloy system. Its fuller implications need further exploring.

X-ray diffractometry was helpful in identifying the matrix microstructure in 'marginal' cases (e.g. in confirming whether 'M' existed in the as-cast condition) and in establishing the identity of the carbides to form namely M_3C, M_5C_2 and M_7C_3 in the as-cast / heat treated conditions. Additionally, the presence of Cu and of Fe-Si-carbide (Fe_8Si_2C) was also established. A complete indexing of diffractograms was possible only if the formation of $CrMn_3$ and Cu_2S was also considered.

EPMA proved helpful in establishing the partitioning behaviour of Mn , Cr and Cu into the matrix and carbide phases which was influenced by heat treatment. It alone established that :

(i) MCs and DCs are M_7C_3/M_3C type carbides, (ii) 'haloed' regions within the matrix are carbides, (iii) dark etching regions between adjoining MCs represented 'matrix regions' with different alloy concentration, and (iv) Cu enriched regions existed in the as-cast/heat treated conditions.

Differential thermal analysis (DTA) revealed two transformations at 540-575°C (matrix transformation) & 960-980°C (carbide transformation). The thermogravimetric data obtained with the help of the DTA demonstrated that the as-cast

microstructures are suitable for high temperature applications upto a service temperature of 600°C . It also proved useful in evaluating the merits of different heat treated microstructures for high temperature applications.

A mathematical model interrelating the weight gain (%TG) with temperature was developed and is of the form

$$\%TG = A1 + A2\ e^{(-A3/T)}$$

Where, TG = weight gain; T= temperature; A1, A2 and A3 are constants.

Weight loss studies , carried out in 5% NaCl solution under stagnant condition clearly brought out the effect of the second phase (MC + DC) [namely the morphology and volume fraction of the MC and the size , shape and distribution of the DCs] in influencing corrosion e.g. plate like morphology and a large volume fraction of the MC had an adverse effect. Similarly a favourable morphology e.g. a rounded or hexagonal morphology of MCs (produced on heat treating from higher temperatures) reduced the adverse effect. In comparison to this, heat treating from lower temperatures adversely affected corrosion resistance due to the diverse nature of the DSPs present (needle and spherical particles). The data thus obtained has useful implications in developing improved corrosion resistant microstructures .

Considering the modelling of the corrosion behaviour (interrelating corrosion rate with the microstructure), the different models developed during the 'on-going' alloy development programme

$$CR = [K1 + K2 (VMC) + K3 (VMC)^2] (NOP)^{K4}$$

where, VMC = volume fraction of MCs only and,

$$CR = [K1' + K2'(VMC) + K3' (VMC)^2] (DF)^{K4'}$$

where, DF = newly evolved term distribution factor (DF) defining DCs & other abbreviations have the same meaning were examined afresh in the light of the experimental data generated in the present study.

Through a critical appraisal it emerged that the final models arrived at in the present investigation are on similar lines as the ones developed before. 3D-plots between CR, VMC & NOP and CR, VMC & DF proved extremely useful in optimizing the microstructures so as to obtain the best in terms of corrosion resistance and deformation behaviour in each of the alloy.

From the point of view of mechanical properties even the as-cast microstructure responded favourably. The austenite bearing microstructures containing needle type DSPs showed somewhat lower compressive strength(CS). However, the

microstructures generated on heat treating from higher temperatures attained high values of CS. The amount and stability of austenite has emerged as the key parameter in influencing the deformation behaviour. The effect of massive carbides on the deformation behaviour was a function of the compatibility, volume fraction and morphology while the effect of DCs was governed by their size, shape and distribution .

Model interrelating compressive strength with hardness is of the form

R = A1 + A2 (H) + A3 (H)^2

where R = CS/H; H = hardness; A1, A2 and A3 are constants.

Thus, summing up, the present investigation is a useful critique on developing new corrosion resistant materials based on basic physical metallurgical principles. Its high points are the modelling of structure-property relations and microstructural optimization .

ACKNOWLEDGEMENT

I express my profound sense of gratitude to my reverend guide, Professor A.K. Patwardhan, Department of Metallurgical Engineering, University of Roorkee, Roorkee for his astute research methodology and inspiration coupled with assiduity and deep insight into the subject. I am greatly indebted to him for his stimulating input of ideas, thought provoking discussions, erudite and meticulous guidance throughout the tenure of my research work.

I am highly grateful to Professor V. Srinivasan, V.C., Jai Naraian Vyas University , Jodhpur and former Principal, MR Engineering College, Jaipur for permitting me to pursue my research work at the University of Roorkee, Roorkee under QIP scheme. I am highly thankful to Dr. Sudhir Verma (IAS), Technical Secretary, Govt. of Rajasthan amd Principal, M.R. Engineering College, Jaipur for extending me all the help at all times.

I am highly thankful to my teacher, Prof. T.V. Rajan, Department of Metallurgical Engineering, M.R. Engineering College, Jaipur for his punctilious guidance, perpetual encouragement, ardent and piognant moral support and personal help at various stages. I am thankful to Prof. M.K. Bhargava, Prof. & Head Dr. H.N. Dharwadkar, Department of Metallurgical

Engineering, M.R. Engineering College, Jaipur for helping me at all the critical moments in every respect.

I am thankful to Dr. D.B. Goel, Professor & Head, Dr. M.L. Kapoor, Professor and all O.C.'s of the concerned laboratories, Department of Metallurgical Engineering, University of Roorkee, Roorkee for extending the help by providing the laboratories and other facilities which enabled me to present the thesis in the present form well in time. I virtually fall short of words while expressing my respect to Prof. D.B. Goel and Dr. M.L. Kapoor who helped me from the very beginning till the completion of the thesis work.

I am thankful to Mr. P.N.V.R.S.S.V. Prasada Rao, Lecturer, Department of metallurgical Engineering, M.R. Engineering College, Jaipur and the then Research Scholar for his help throughout my period of stay at Roorkee. His generous help greatly eased the task.

I am grateful to Dr. J.L. Gaindher, Professor, Department of Mechanical and Industrial Engineering, Prof. S. Prakash, Dr. V.K. Tewari, Dr. S.K. Nath, Department of Metallurgical Engineering for their continuous help, support and for their useful discussions and suggestions extended to me. The help from Dr.

to Mr. Anil Kumar, Mrs. Rekha Sharma and Mr. K.N.R. Jual for the help rendered.

I express my sincere gratitude to Prof. K.R. Soni, Head and Dr. C.L. Arora, Professor, Department of Physics, MREC, Jaipur for their family-and-generous touch during the period of my research work.

It is with stupendous delight I express my whole-hearted indebtedness to Dr. Surendra Kumar, Chemical Engineering Department, University of Roorkee, who always boosted my morale with his brotherly touch. I sincerely appreciate his deep personal involvement. The constant and continuous help by Sarvasri S.C. Kaushik, S.K. Seth, S.P. Anand. J.P. Sharma, Madhu Kumar, S.N. Kaushik, V.K. Tyagi, Vidya Prakash, Kailash Chand, Prem Singh and Ms. Vijay Laxmi is highly appreciated.

I fall short of words to express my inner core of heart for my eldest brother, Dr. T.P. Sharma, Head, Fire Research Laboratory, CBRI, Roorkee, who not only provided me the best facilities available at Roorkee but also took away lion's share out of my responsibilities at the critical juncture of the thesis work by rendering me his moral, monetory and physical help.

I would like to emphasis the support, forbearance and inspiration from my in-laws.

I sincerly express my grateful to Mr. Suvir Singh, Mr. R.S. Chimote, Mr. Sushil Kumar, Mr. Jalaj Prashar, Mr. Sewa Ram, Mr. Rajiv Bansal, Mr. Rajiv Kasyap and Ms. Deepti Gupta for their timely and constant efforts during the completion of my thesis work.

I am thankful to all the family members of Dr. A.K. Patwardhan, Dr. S. Kumar, Mr. Suvir Singh, Mr. R.S. Chimote for their kind support and help. I too sincerely oppologise to family members of Mr. Suvir Singh, Mr. R.S. Chimote, Mr. Sushil Kumar, Mr. Jalaj Prashar, Mr. Sewa Ram, Mr. Rajiv Bansal, Mr. Rajiv Kasyap and Ms. Deepti Gupta for inconvenience caused due to strenous work load of the thesis work.

Last but not the least, I wish to record most affectionately and with great indebtedness, the patience and excellent understanding shown by my wife Usha, daughter Avantika and son Anu Ayam to bear the gross negligence during the entire period of my research work.

In the strenuous task of my doctoral research, I received directly and indirectly assistance and help from my inumerable

colleagues with special reference to Mr. K.L. Narang and Mr. A.K. Bhargava. To acknowledge their whole-hearted assistance, I virtually fall short of words; therefore, I am leaving this acknowledgement incomplete ..... in their reminiscences.

(C.P. SHARMA)

CHAPTER I

INTRODUCTION TO CAST IRONS

1.1 INTRODUCTION

Cast iron is a generic term used to identify a large family of ferrous alloys which in the simplest form are regarded as binary alloys of iron and carbon [Stickle (S15), Walton (W1)]. The lower limit of carbon may exceed its maximum solubility in austenite. Although the upper limit may approach the carbon content of iron carbide (Fe_3C), it rarely exceeds 4 per cent [Avner (A8)] because it is difficult to produce binary alloys with 'C' in excess of 4 % commercially owing to economic and technical limitations. Besides carbon, varying quantities of other elements such as silicon, manganese, phosphorus and sulphur are always present in cast irons. The role of silicon is so dominant that the term cast iron is usually applied to a series of iron, carbon and silicon alloys [Lakhtin (L3)].

Because production cost of pig iron, the raw material for making cast irons, is relatively low as compared with other alloys, and since no expensive refining process is necessary, cast iron is regarded as low priced engineering material.

Cast irons offer a wide range of properties namely strength, hardness, machinability, wear resistance, abrasion resistance, corrosion & oxidation resistance . Further more, the founding characterstics of cast irons such as yield, fluidity, shrinkage, soundness, ease of production, and others make it an ideal choice as a cast material. In fact the ease with which a wide range of properties can be attained in them makes them an important class of engineering material but also ensures their continued and wide-spread use even as ' high-tech ' materials [Heine (H5)].

Since many types of cast irons have been developed and are in use, it is desirable to review the underlying physical metallurgical principles critically in order to project an over all picture of the family of cast irons to arrive at the 'tehnologically significant ' and ' technologically deficient ' regimes. Evidently the starting point for such an agenda is the Fe-C diagram.

Though Fe-C diagram is of great value, it is not an equilibrium diagram in the true sense since cementite has a natural tendency to decompose into iron (ferrite) and carbon (graphite). However, once formed, cementite is quite stable and for practical purposes is regarded as an equilibrium phase.

The equilibrium between iron and graphite is shown in solid lines whereas the dashed lines represent the metastable relationship between iron and cementite (Figure. 1.1) [Askeland (A4)]. Although the former represents stable reactions (i.e. all structures should eventually have graphite), nucleation of graphite in iron- carbon alloys is so difficult that one almost always obtains undercooling (> 6°C) which allows the metastable reactions to occur [Askeland (A4)]. Figure 1.2 [Hillert (H9)] shows the variation of the growth kinetics of the graphite and carbide eutectics as a function of temperature. The diagram shows that in the temperature range 1155-1148°C only the graphite phase can exist. If nucleated, it will grow without competition from the carbide. Just below the equilibrium temperature for the carbide phase, its growth rate is lower than that for graphite. This changes rapidly with decreasing temperature, so that the curves cross at approximately 2° C below the carbide equilibrium; in the prevailing situation carbide phase will grow faster than graphite and hence will dominate the structure as the temperature further decreases [Minkoff (M13)].

Addition of silicon increases the temperature difference between the "stable" and "metastable" eutectic reactions (Figure. 1.3) [Askeland (A4)]. When a liquid iron-carbon-silicon alloy cools, there is a large temperature interval within which stable

iron- graphite eutectic reaction can take place. If solidification occurs between the two eutectic temperatures (Figure. 1.4) [Askeland (A5)], a graphite-containing iron, such as grey, ductile or compacted graphite, is produced. If solidification occurs below the lower eutectic temperature, a white iron forms. Conditions favouring the occurrence of the two eutectic reactions are shown in Table 1.1 [Askeland (A4)]. In some instances, both the eutectic reactions may occur e.g. mottled irons begin to solidify above the lower eutectic temperature (LET) and solidification is completed below it (LET) [Askeland (A4)].

1.2 EFFECT OF ELEMENTS NORMALLY PRESENT ON IRON-GRAPHITE / CEMENTITE 'EQUILIBRIUM'

Presence of elements would influence the general state of equilibrium as well as the state in which carbon could exist. Carbon may be present either in the combined form (as carbide) or in free form (as graphite). This aspect has a major influence on the physical and mechanical properties. The term total carbon (TC) represents the sum of the free and combined carbon (including carbon in solution).

For the Fe-C alloys, the eutectic occurs at 4.3 per cent carbon. Alloys above this carbon level are termed hypereutectics and those below it as hypoeutectics. The hypereutectic compositions may develop coarse open-grained structure and comparatively large flakes of "kish" graphite when cooled slowly. Hypoeutectic alloys, on the other hand, attain relatively fine graphite and denser and tighter structures. The aforesaid tendencies become more marked as the carbon content of the hypereutectics is raised and that of the hypoeutectics lowered.

Presence of unintentionally added elements affects the solubility of carbon. Both silicon and phosphorus reduce the amount of carbon required to form the eutectic by 0.3 per cent for each 1 weight per cent of the element added [Strauss (S16)]. This gives rise to a concept known as the "carbon equivalent" which is employed as a basis to define cast irons. Carbon equivalent (CE) is given by the expression,

$$CE = \%TC + (\%Si + \%P)/3$$

For alloyed irons, the expression would also include effect(s) from other elements. The eutectic composition is always near 4.3% CE. Any cast iron with a CE less than 4.3% is hypoeutectic whereas any with a CE greater than 4.3% is

hypereutectic. A hypoeutectic alloy will have lower carbon and silicon contents whereas hypereutectic alloy will have higher carbon and silicon contents. In general, the lower the CE value, the greater the tendency for an iron to solidify white or mottled [Askeland (A4)].

The total carbon and silicon contents of an alloy, as reflected in the CE value, not only establish the solidification temperature range of the alloy, but are also related to its foundry characteristics and properties. Cast irons of the same CE value may be obtained with different carbon and silicon values and consequently differing in properties.

The lower the carbon equivalent value below 4.3 the more likely it is that undercooling will take place and graphitization occurs with increasing reluctance and will become completely suppressed if the undercooling attains the temperature at which the carbide eutectic forms. Very slow cooling encourages the precipitation and growth of graphite [Strauss (S16)].

Addition of silicon shifts the eutectic composition to the left and lowers the eutectic temperature. Silicon is a potent graphitizer and therefore the silicon bearing cast irons solidify as per the stable iron-graphite system unless the graphitizing tendency is offset by adding carbide forming element(s). Carbon

separates as primary graphite in the form of flakes. Such an happening would preclude any alteration of its shape. Presence of graphite flakes imparts discontinuity to the matrix and is responsible for the low strength and low ductility of grey irons [Avner (A9)]. Silicon dissolves in the iron forming a solid solution which increases hardness as silicon increases. The presence of this dissolved silicon in the matrix, up to a certain point also adds to its strength. This can be understood by the fact that the strength of Fe-4% Si alloy is almost double and that of Fe - 2% Si alloy is about 1.6 times the strength of pure iron [Lorig (L5)].

The main function of manganese in cast irons is to counteract the undesirable effect of sulphur by forming manganese sulphide. It is lighter than iron sulphide and floats out of the molten iron as slag. In the absence of Mn, sulphur is present as iron sulphide which is retained in the melt and deposited around the grain boundaries inducing hot shortness.

The indirect effect of Mn, therefore, is to promote graphitization by combining with sulphur [Higgins (H7)]. For manganese to act as an alloying element , its amount present must exceed that which will combine with sulphur i.e. theoritically it should be 1.7 times the sulphur content [Walton

7

(W2)]. However, a formulation of practical interest is given by the relation :

$$\% \text{ Mn} = \% \text{ S} \times 1.7 + 0.15$$

Manganese in excess of that required to combine with the sulphur stabilizes carbide. This leads to an increase in the chilling tendency and therefore the hardness [Askeland (A5), Avner (A9)].

When present in amounts ranging from 0.40 to 1.00 per cent, manganese may increase machinability. In amounts less than 1.00 per cent, manganese has little effect on mechanical properties. The addition of manganese in excess of 1.25 per cent increases strength, hardness, chill and resistance to wear but decreases machinability [Higgins (H7)]. As will be evident, manganese can play an effective role in developing alloyed irons.

Sulphur has a marked influence on hardening. In the absence of sufficient manganese, sulphur increases stability of the iron carbide very markedly and also the chilling tendency. Sulphur renders molten iron sluggish which leads to defects such as short running and pinholes due to entrapment of mould and other gases. Undesirable effects of sulphur can be counteracted by manganese additions. Manganese also raises the fluidity of the molten cast

iron [Avner (A9), Higgins (H7)].

The solid solubility of phosphorus is limited in austenite and so phosphorus in cast irons is present as iron phosphide, which is a constituent of iron-iron phosphide eutectic in grey irons and the iron-iron phosphide-cementite eutectic in mottled and white irons. Phosphides are similar to carbides. They cause machining problems but are not eliminated by heat treatment. The eutectic has a relatively low melting point (960°C) and consequently phosphorous bearing irons have better fluidity.

Phosphorus has a negligible effect on the stability of cementite, but its direct effect is to promote hardness and brittleness due to the large volume of phosphide eutectic which a comparatively small amount of phosphorus will produce. Phosphorus must be kept low in irons where shock resistance is important. Increasing amounts of silicon reduce the effect of phosphorus.

Phosphorus bearing cast irons exhibit improved wear resistance and good resistance to severe corrosive attack, notably from hydrochloric, sulphuric and acetic acids .

High phosphorus content has been associated with the segregation of molybdenum, chromium, vanadium and tungsten. This leaves areas of the matrix depleted in these elements and reduces

strength. 'Phosphide eutectic liquid' at cell boundaries creates a mushy state that is difficult to feed. This condition creates high eutectic solidification forces within the outer solidifying shell, causing mould wall movement and a requirement for feed metal in the final stages of solidification. This can lead to shrinkage porosity. Phosphorus increases fluidity and extends the range of eutectic freezing, thus increasing primary graphitization when the silicon content is high and phosphorus content is low. It is therefore useful in very thin castings where a less fluid iron may not take a perfect impression of the mould.

The elements (Si, Mn, S & P) discussed above, though normally present in all varieties of cast irons, have a major influence on the soundness of the castings. Once they are taken care of, it becomes relatively simpler to add the main alloying elements for the specific effect(s) they impart.

1.3 GENERAL CLASSIFICATION

Cast irons are most extensively used casting alloys despite a considerable decrease in their production during the past decade. Ability to produce complex shapes at relatively low cost and the wide range of properties that can be achieved by careful control of chemical composition, solidification process and heat

treatment make them an ideal choice for a number of applications so much so that there could be a strong case for classifying them as high-tech materials.Cast irons can be categorized depending upon the (i) form of carbon, (ii) matrix microstructure and (iii) applications.

A simple classification would be to categorize them into general purpose and special purpose [Elliott (E1)]. The former, as the name suggests, are cast irons used for general engineering applications and include grey irons, malleable irons, nodular irons and compacted graphite irons. Specifications exists for all types except for the recently developed compacted graphite variety .

Special purpose cast irons include white and alloy cast irons which are mainly used for applications demanding enhanced abrasion, corrosion or heat resistance.

Austempered ductile irons are a new introduction to the family of cast irons. A detailed and critical review of literature on austempered cast irons is available in few recent publications [Janowak (J6), Janowak (J7), Shiokawa (S8), Dorazil (D6)].

1.3.1 GENERAL PURPOSE CAST IRONS

The commonly employed cast irons namely grey, malleable and nodular are shown schematically in Figure. 1.5 [Askeland (A4)] which also illustrates features of a more recently developed iron called the compacted graphite cast iron. The typical properties and principal applications of each of the grades has been discussed in detail by Gillbert [Gillbert (G1)]. The basis of deciding whether to select an ordinary grey iron , or an S.G. iron or a malleable iron for an end application comprises the economic and the technical considerations. Grey irons offer the lowest cost in cost option of producing sound castings. It is , however, not easy to choose between the remaining ones, namely between the S.G. and the malleable irons, malleable irons are more difficult to cast because the starting microstructure is a white iron. This automatically introduces section size limitations. Moreover, the cost incurred in malleabilizing is large. As against this S.G.irons although not requiring a long duration heat treatment may not be able to attain the expected/stipulated levels of toughness. Similarly, it may become necessary to heat treat an S.G. iron to introduce uniformity in properties ; similarly annealing may be necessitated to improve machinability [Higgins (H8)].

Compacted graphite cast irons [Higgins (H8), Minkoff (M14), Cox (C4), Metals Hand Book (M9), Walton (W3)], which were originally considered to be a degenerate form of spheroidal iron, exhibit a microstructure midway between grey irons and spheroidal irons. Graphite appears as short, thick flakes with rounded ends and can therefore be distinguished from the conventional flake graphite [Minkoff (M14)]. SEM studies have revealed that compacted graphite comprises interconnected branches and is more akin to flakes than the completely isolated nodules present in spheroidal grey irons [Minkoff (M14)].

Compacted graphite iron is produced when molten iron of near eutectic composition is first de-sulphurised in the laddle and then treated at 1400°C with a single alloy containing appropriate amounts of magnesium, titanium and cerium so that the resultant iron contains Mg (0.015-0.030%), Ti (0.06 - 0.13%) and Ce (a trace). The presence of magnesium tends to produce spheroidal graphite (as it does in S.G. iron) and this is controlled by the restraining tendency of titanium which makes the amount of the magnesium less critical [Higgins (H8)].

A compacted iron exhibits superior tensile strength, stiffness and ductility, fatigue life, impact resistance and elevated temperature properties compared with grey iron of a

similar matrix structure. In general, compacted graphite irons effectively fill the mechanical and physical property void between grey and nodular irons. Table 1.2 [Cox (C4)] shows mechanical and physical properties of compacted irons whereas Table 1.3 [Metals Hand Book (M9), Walton (W3)] provides a comparison between the mechanical and physical properties of compacted graphite , grey and nodular irons.

A unique combination of high strength, good ductility and high thermal conductivity coupled with superior resistance to cracking and distortion (as compared to both grey and nodular iron) make compacted graphite irons an ideal engineering material. These irons are very well suited as materials for ingot moulds. In so doing the service life is improved by as much as 70 per cent. Good elevated temperature properties have resulted in their being used for cylinder heads, gear pumps, eccentric gears, exhaust manifolds, brake drums, discs and piston rings.

1.3.2 SPECIAL PURPOSE CAST IRONS

The term "special purpose cast irons" has been used to designate white irons and alloy grey cast irons exhibiting resistance to corrosion, abrasion and thermal shock. Presence of alloying element(s) is primarily responsible for introducing

these attributes. Extensive information is available on the effect of alloying elements on the properties of different grades of cast irons. As such these effects are not being separately discussed and would be considered as a part of the discussion on different grades of cast irons.

Special purpose cast irons [Elliott (E1)] can be divided into two broad classes namely white and grey irons depending upon whether carbon is present in the combined form or in the free form. The following sections describe some alloy grey irons of commercial importance.

1.3.2.1 SILAL

Silal [Barton (B3), walton (W4)] one of the earliest heat resistant irons developed by Norbury and Morgan of the British Cast Iron Research Association (BCIRA), is a trade name given to silicon bearing heat resisting irons. Basically silal can be categorized as silicon alloyed grey iron containing 4 to 6% silicon. The general microstructure of Silal consists of graphite in a completely ferritic matrix.

The size and the distribution of the graphite flakes has an important bearing on the heat and oxidation resistance. Fine undercooled graphite has been found to impart the best heat

resistance. Similarly, the formation of the undesirable hypereutectic "kish" graphite should be avoided.

The carbon content of silal depends upon the silicon content and is adjusted so as to retain a hypoeutectic composition and avoid primary graphitization.

For the production of a 5 per cent silicon iron the total carbon content should be less than 2.7 per cent and lower values will reduce the amount of graphite present and thereby improve mechanical properties.

Silicon increases oxidation resistance, up to 6 per cent, by forming a resistant oxide film and then a silicate film which provides resistance to the transport of oxygen atoms into the metal and to the diffusion of metal atoms towards the surface. Silicon also raises the critical temperature at which ferrite transforms to austenite thereby expanding the useful temperature range of application with respect to resistance to growth.

Silicon content of silal is governed by the service temperature. The necessity of relating the silicon content to the service temperature has been well illustrated by White, Rice and Elsea [White (W7)] and Maitland and Huges [Maitland (M3)]. Scaling and growth resitance are increased by increasing the

silicon content, provided that the temperature of service is lower than the critical temperature range. In amounts exceeding 5 per cent, silicon reduces toughness and increases the brittle-ductile transition to above room temperature. The aforesaid considerations form the basis of the optimizing the silicon content to prevent/resist growth. For optimum in terms of properties, the Si content should be approximately 4.5 to 6.5%. Such a composition is very well suited for temperatures ranging from room temperature up to 900°C.

It has been suggested that the benefit of increasing the silicon content up to 4.5 - 5.5 per cent, is due to (a) the production of a completely ferritic matrix, thereby avoiding the growth associated with the decomposition of pearlite; (b) a degree of surface passivation conferred by the silicon which, however, probably breaks down at high service temperature; (c) raising the critical transformation temperature, and thus avoiding the stresses and growth associated with the ferrite to austenite change.

For use at higher service temperatures (>900°C), the silicon content is raised to about 11% The disadvantage of a higher silicon content is that the iron is weaker and more brittle at room temperature than a 5% silicon iron.

The inherent brittleness of Silal at normal temperatures restricts its applications. However this brittlenes is not a problem if the service temperatures are above 260°C. These irons have been used successfully for furnace and stoker parts, for burner nozzles, and for trays used in heat treating other metals.

Mechanical properties of Silal can be improved through alloying. Addition of small quantities of chromium (0.5-1.0%) refines the graphite and increases the density and strength significantly. A further increase in the chromium content makes the microstructure uniform but also leads to the formation of free carbides.

Small amounts of copper and nickel in the presence of chromium favourably influence the mechanical and heat resistant properties.

The ductile grades (consisting of spheroidal graphite) containing 4 to 6% silicon account for the major tonnage presently used by the industrial sector. The higher strength and ductility of these irons qualify them for more rigorous service. Through the mechanism of solution strengthening, silicon contributes to the enhancement of the mechanical properties of ductile irons, particalarly in the temperature range 370 to 540°C.

Spheroidal graphite Silal is superior to conventional Silal (flake graphite Silal) from the view point of oxidation resistance at elevated temperature. This is mainly due to the fact that the oxide layer formed in S.G. Silal is not broken by graphite precipitation, shows less cracking and adheres well to the surface. Thus penetretion by oxygen is difficult and the S.G. Silal even after oxidation exposes less surface areas and oxygen penetration through these is less.

The as-cast microstructure of the ductile (S.G.) Silal containing 4 to 5% silicon is predominantly ferritic, but small amounts of eutectic carbide and pearlite may persist at grain boundaries. The presence of these constituents contributes to a tendency towards brittleness. These irons are generally annealed to eliminate the eutectic carbides and pearlite, or, to at least, minimise their adverse effect.

The 4% silicon ductile irons can be alloyed with 0.6 to 2.0% molybdenum to obtain a combination of adequate strength and ductility at room temperature and good strength properties and resistance to oxidation at elevated temperatures. Molybdenum although added primarily to develop high temperature mechanical properties in the 4% ductile silicon irons, also increases the strength at room temperature.

Although there is a continous increase in the creep rupture strength and a reduction in creep rates as molybdenum contents are increased up to 2.5%, the greatest response to increased molybdenum contents is realised from the additions of 0.5 to 1.0% molybdenum.

Because of their relatively low cost, their low creep rates at temperatures in the 700 to 820°C range and good resistance to oxidation, the molybdenum alloyed, 4% silicon irons are attractive materials for the production of some automobile and truck turbochargers. A 1% molybdenum content is used for special engine exhaust manifolds and heat treating racks.

1.3.2.2 NICROSILAL

It is a heat resistant alloy cast iron developed by BCIRA in 1930. The approximate range of composition of Nicrosilal is: total carbon 1.6 - 2.2 per cent; silicon 4.0 - 4.5 per cent; manganese 0.6 - 1.2 per cent; nickel 18.0 - 22.0 per cent; chromium 2.0 - 4.0 per cent; phosphorus 0.1 - 0.5 per cent. The basic purpose of the development of Nicrosilal [Barton (B3)] was to have a cast iron with superior or at least equivalent heat resistance to that of Silal but with better ductility and toughness. This was achieved through alloying with nickel and chromium.

The general microstructure comprises of graphite in a predominantly austentic matrix. For the best mechanical properties and oxidation resitance the graphite should be fine and preferably undercooled. Chromium bearing carbides are also present when chromium content exceeds about 1.8 per cent. The morphology of the carbides varies with the graphite structure, being acicular with the undercooled graphite, and relatively coarse and massive when random graphite flakes are produced/present.

Optimum properties are obtained at 4.5-5.0 per cent silicon. Lowering the silicon content reduces heat resistance. A higher silicon content lowers the solubility of carbon in austenite. An increase in silicon content thus adversely affects the stability of austenite and favours the formation of silico-ferrite, a brittle phase. Stability of austenite can be restored to a desired level by adding austenite stabilizer Ni.

The addition of nickel to this material imparts an initial hardening up to about 10 per cent nickel followed by a gradual softening of the material until a fully austenitic matrix is obtained.

As both silicon and nickel decrease the carbon content in eutectic the carbon content of these cast irons rarely exceeds

1.8 to 2.0 per cent. Increased carbon content results in the production of coarse primary graphite. A minimum of 18 per cent nickel is maintained to stabilize austenitic matrix. A chromium content of at least 1.8 per cent is also always present.

A small amount of the chromium enters into solution in the austenite, but most of it is present as carbide and thus imparts strength to the matrix. Enhanced wear and heat resistance can be obtained by increasing the chromium content up to about 4 per cent.

The heat resistance of Nicrosilal is dependent upon its high silicon content coupled with the presence of a stable austenitic matrix. Heating this iron within the range 400-700°C causes instability of the austenite resulting in the formation of martensite and thus making the material magnetic and hard. Subsequent cooling to room temperature from the temperature range results in the dimensional changes and embrittlement which lead to cracking. This problem can be overcome by increasing the nickel content.

Nicrosilal exhibits excellent physical and mechanical properties at room temperature as well as at elevated temperatures. It is superior to Silal in terms of toughness,

thermal shock resistance and resistance to scaling. It offers very high (even better than Ni-Resist) oxidation resistance up to 1000°C and can be safely employed in sulphur bearing atmospheres.

1.3.2.3 HIGH SILICON IRON

High silicon cast irons [Barton (B3), Metals Hand Book (M10), Shreir (S9)], containing silicon between 14-16 per cent, are perhaps the cheapest corrosion resistant irons offering maximum resistance to acids. The alloys resist oxidizing and non-oxidizing acids better than any other commonly employed metallic materials. For this reason, these cast irons are popularly known as acid - resisting cast irons. Their discovery is normally credited to Jouve, a french metallurgist, in 1908.

Their microstructures (upto 15.2 per cent silicon) comprise a solid solution (silico-ferrite) containing free carbon distributed as fine graphite flakes [Hurst (H13)]. In amounts in excess of 15.2 per cent silicon, both ∩ and ε phases appear in the microstructure [Shreir (S9)]. Their presence considerably increases the brittleness of the material. These phases can be identified under polarized light. In view of this, the silicon content is normally restricted within the range 14.25 to 15.25 per cent though a higher level of silicon is required to give maximum corrosion resistance, specially to hydrochloric acid.

Compositions and properties of the high silicon irons are given in the Table 1.4(a) & 1.4(b) [Boyer (B10)].

High silicon irons are basically low strength brittle materials exhibiting poor thermal and mechanical shock resistance. An attempt has been made to produce high silicon iron with a nodular graphite structure for improving the mechanical properties [Dumitseseu (D7)]. It has been observed that nodular graphite silicon irons have not proved useful which confirms that the low strength and brittleness of high silicon irons is essentially due to the brittle matrix rather than the graphite form.

Their excessive hardness makes them virtually unmachinable except by grinding. The mechanical properties of high silicon irons are summarized in Table 1.4(b) [Boyer (B10)]. Mechanical strength and shock resistance can be improved by lowering the silicon content to about 12 per cent; however the corrosion resistance is significantly reduced thereby restricting the applications to those situations wherein the loss in corrosion resitance has a minimal effect on service life or is offset by the benefit derived from a higher strength [Metals Hand Book (M10)].

Resistance to attack by hydrochloric acids can also be improved by adding 3 to 4 per cent molybdenum or 3 to 5 per cent chromium to the basic composition. These addition also tend to increase the brittleness of the iron. The improved corrosion resistance of molybdenum bearing high silicon irons may be attributed to the formation of extremely stable complex carbides with the consequent elimination of graphite [Hurst (H13)]. Chromium also gives a similar beneficial effect. Good corrosion- erosion resistance is primarily due to its high inherent hardness.

High silicon cast irons are highly resistant to solutions of organic acids at all concentrations and temperatures but inferior to ordinary grey irons in their resistance to alkali attack [Hurst (H13)].

High silicon cast irons are a low strength, brittle materials and are very susceptible to cracking owing to a build up of internal stresses associated with differential cooling rates of various sections. These stresses may be removed by stripping the castings from the moulds before a temperature of 800°C is reached and placing them in an annealing furnace at 800-850°C. The castings are allowed to remain in the furnace for 4-5 hours, after which they are cooled to room temperature over a period of about 30 hours [Angus (A2)].

The excellent corrosion resistance of high silicon irons is largely due to the presence of silica-like oxide film. This film is a corrosion product which forms during exposure to the environment. This film prevents further corrosion in many media. On initial exposure to a corrosive medium, the iron is attacked by aggrassive ions and iron atoms are leached out of the silico-ferrite lattice; the corrosion rate is high during initial exposure. The silicon atoms remaining in the matrix of the iron are oxidized to form silicon-oxygen compounds which react with water at the metal surface to form an adherent film. The film continues to develop and harden with time thereby improving the efficacy of the protection it imparts [Walton (W4)]. The maximum advantage of protective film is achieved at silicon contents ≥14.25% [Dumitsescu (D7)]. Hydrofluoric acid is capable of dissolving this film and thus the material offers no resistance to hydrofluoric acid. Also the resistance to sulphurous acid is very poor.

High silicon irons exhibit good resistance to sulphuric, nitric and mixed (sulphuric and nitric) acids at all concentrations and temperatures. The resistance to hydrochloric acid is somewhat inferior but can be improved upon by increasing the silicon content to levels of 16 to 18 per cent, a modification which causes the irons to become more brittle.

High silicon cast irons are used extensively in equipment for the production of sulphuric and nitric acid; for fertilizer, textile, and explosives manufacturer; for sewage disposal and water treatment; for handling mineral acids in petroleum refining, and in metal cleaning or pickling; in electroplating; for processing of paper, beverages, and paints and pigments; and as anodes for the impressed current, cathodic protection of iron pipes or other ferrous vessels buried in the soil. Specific castings of high silicon irons include pump rotors, agitators, kettles, evaporators, separator towers and Rachid rings, tank outlets, crucibles, insoluable anodes, and pipe and fitting for plumbing in chemical laboratories of hospitals, colleges, and industry. The size of castings may vary from small pump rotors and laboratory sink fittings to tower sections 1.22m in diameter and 1.22 mm high.

1.3.2.4 NI-RESIST CAST IRONS

'Ni-Resist' is a trade name used for a group of high nickel cast irons containing sufficient nickel to produce an austenitic matrix. This matrix is tough, heat-resisting and stable under chemical attack giving the irons outstanding performance in contact with a wide range of commonly occuring corrosives. The irons are not completely stainless, but they form a thin, closely

adhering film of rust which prevents further corrosion and does not flake off to contaminate the product handled [Anant Narayan (A1)].

These (Ni-Resist) irons contain nickel ranging from 14 to 36 per cent, chromium from 1.6 to 6.0 per cent and molybdenum up to 1 per cent. As does in stainless steels, the alloy content of the Ni-Resist irons gives them good resitance to corrosion, erosion and the destructive effects of moderately high temperatures. They show advantage in many environments when compared with carbon steel and ordinary cast irons. Tougher than grey irons, Ni-Resist irons have good castability and machinability [Anant Narayan (A1)].

There are two main classes of Ni-Resist, the copper containing and the copper free (Table 1.5a) [Metals Hand Book (M10), Inco (I2)]. Both the types contain chromium which imparts hardness and stiffness to the material. Presence of chromium also ensures good machinability which is otherwise poor due to greater toughness of the austenitic matrix.

Microstructure of Ni-Resist irons comprises of graphite flakes in an austenitic matrix. Presence of carbides would depend upon the presence of chromium [Barton (B3)].

Though the Ni-Resist irons are tougher and more resistant to shock than conventional grey cast irons, the fact that the graphite is present in the same weakening flake form inhibits possible improvements. Much better strength and impact properties can, however, be obtained by treating the iron so that the graphite appears in the spheroidal form whose weakening effect on the austenitic matrix is negligible. The improved Ni-Resist irons of the S.G.Ni-Resist series have better mechanical properties than those of their-flake graphite counterparts and this has considerably extended their field of use [Anant Narayan (A1)].

Ni-resist irons, thus, are also classified on the basis of graphite morphology - flake and spheroidal graphite. To distinguish the spheroidal graphite irons from the flake ones, the prefix 'D' has been used. The composition ranges are given in Table 1.6a [INCO (I2)].

Unlike high silicon and high chromium irons, corrosion resistance of Ni-Resist irons is due to high nickel content rather than to the presence of an inert oxide surface film [Metals Hand Book (M10), INCO (I2)]. Ni-Resist irons offer high resistance to the corrosive action of sulphuric acid and are perhaps the most economical in resisting attack by sulphuric

acid. Ni-Resist irons do not perform well in hydrochloric acid and are unsuitable in resisting attack by nitric acids. They offer excellent resistance to caustic soda over a wide range of concentrations and temperatures.

Ni-Resist irons, unlike the high silicon and high chromium irons, are not truely rustless. However, the rust film which develops over the ·first few years restricts further corrosion [INCO (I2), INCO (I5)]. Copper bearing Ni-Resist irons produce a blue coloured corrosion product not looked at favourably by food, soap and cosmetic industries. Although the mechanical properties (Table 1.5b & 1.6b) [INCO (I2)] of flake graphite and spheroidal graphite vary considerably (the latter one having superior properties), the corrosion behaviour of the two varieties is nearly similar. This is a reflection of the superiority of flake morphology in resisting corrosion.

(A) FLAKE GRAPHITE NI-RESIST IRONS

There are five basic types of Ni-Resist irons (Table 1.5a) two of which have specified modifications [INCO (I2), (I3), (I4)] : Types 1 and 2 are used interchangeably in many corrosion and wear resistant applications. Both are specially suited to heavy metal-to-metal wear service. Type 1 has some advantages over the other types in handling mineral-acid

corrosives and salt water and where maximum expansivity is desired such as in piston ring inserts for matching the expansivity of aluminium. Type 1b has superior corrosion-erosion resistance in comparison with Type 1, and is harder and stronger.

Type 2, because of its wide use in corrosive environments, is the most commonly used. It is preferred for heat and oxidation resistance to 700°C and in steam service. It is also used for handling caustics, alkalies, ammonical solutions, food products, rayon, plastics and similar environments where freedom from copper contamination is desired. Type 2b is specially recommended for heat applications up to 815°C. Uses include gas turbine parts, exhaust manifolds and turbochargers. If machining is required, the chromium level should be kept between 3.0 to 4.0%. The greater hardness of type 2b makes it suitable for resistance to abrasive wear with corrosion, but it is not suited for metal-to-metal wear.

Type 3 is recommended for severe thermal shock service between room temperature and 230°C. At temperatures between 230 and 815°C without severe thermal shock, Type 3 can also be used for applications such as diesel exhaust manifolds and

31

turbochargers. This type offers high resistance to erosion in wet steam and corrosion slurries.

Type 4 is recommended when stain resistance is required. This type is superior to other types of Ni-Resist in resisting erosion, corrosion and oxidation.

Type 5 offers minimum thermal expansivity which provides dimensional stability for machine tool parts, forming dies, steam turbines, scientific instruments and expansion joints. It can be preferred over the other types of Ni-Resist to minimize thermal shock stresses up to 420°C.

(i) HEAT TREATMENT

Ni-Resist castings can be stress relieved at 620-675°C to remove residual casting stresses. However, large, relatively thin section casting such as large pump diffusers or water boxes should be mould-cooled to 315°C before shakeout rather than furnace stress relieved.

If Ni-Resist castings are fully alloyed but are higher in hardness than expected, they can be softened by heat treatment. Annealing at 980-1040° C for 1/2 to 5 hours will break down some of the carbides and most of those remaining will be spheroidized.

Castings with hardness values greater than 190 BHN can be softened in this manner without any adverse effect upon the strength. This does not apply to types containing 4% or more chromium such as type 4. The best results are obviously obtained when the carbides have become completely spheroidized.

(ii) WEAR AND GALLING RESISTANCE

Because Ni-Resist, (just as grey iron) has graphite particles distributed throughout its structure, it is highly resitant to galling and to metal - to - metal wear. In the hardness range of 130-175 BHN, the alloys have optimum metal - to - metal wear properties and exhibit a fine carbide structure. For moving parts operating to 815°C Ni-Resist can be used to combat rubbing wear, galling and heat oxidation.

The Ni-Resist alloys have shown unusual ability to resist a combination of corrosion and erosion, specially in applications such as pump and valve parts subjected to marked erosion effects by suspended solids, velocity of the liquid and by the water droplets in wet steam.

(iii) CORROSION RESISTANCE

The austenitic Ni-Resist alloys are intermediate in corrosion resistance between grey cast iron and austenitic Cr-Ni

stainless steels. There are exceptions to this. For instance, in very mild environments, both grey cast irons and the Ni-Resists may corrode at low rates.

The largest application of the Ni-Resist alloys is in the petroleum industry. In hydrogen sulphide environments Ni-Resist alloys develop a protective sulphide corrosion product that results in a very low corrosion rate. Ni-Resist pumps and valves are particularly well suited for offshore oil well applications where their resistance to brines and marine atmospheres make them preferred construction materials.

Generally Ni-Resist alloys are ideally suited to seawater handling systems for a number of important applications [INCO (12)]. They provide significant "corrosion" advantages over unalloyed cast irons. The excellent erosion-corrosion resistance of the Ni- Resist alloys has resulted in extensive applications for pump and valve components in seawater handling systems.

Ni-Resist is cathodic to galvanized steel, aluminium alloys, steel and unalloyed cast irons, and is anodic to the various copper alloys, stainless steels and nickel alloys. The latter alloys, particularly the austenitic stainless steels, are

frequently used in combination with Ni-Resist alloys in seawater without introducing serious galvanic corrosion problems.

The adherent character of the scale formed on Ni-Resist castings at elevated temperatures is important for applications such as gas turbines, exhaust manifolds and turbocharger components.

(B) S.G. NI-RESIST IRONS

Ductile Ni-Resists [INCO (I2), (I3), (I4)] are similar to conventional Ni-Resist compositions but have been treated with Mg to convert the graphite from flake form to spheroids. The ductile family of Ni-Resists is available in every type except Type 1 which because of its high Cu content, does not respond properly to Mg teatment. There are, in addition, several modifications of Type 2 to 5 including a low temperature grade, D-2M and a high temperature, dimensionally stable grade, D-5B.

Type D-2 is recommended for service requiring resistance to corrosion, erosion, frictional wear and temperature up to 760° C.

Type D-2B is recommended for superior resistance to neutral and reducing salts and where higher resistance to erosion and oxidation than that afforded by Type D-2 is desired.

Type D-2C is recommended where resistance to heat and corrosion is less severe and where high ductility is desired.

Type D-2M was developed for use at cryogenic temperatures. Its austenitic matrix is stable to at least as low as -250^0C and thus it retains toughness adequate for most applications down to that temperature.

Type D-3 is recommended for thermal shock service. This type, in addition to having excellent elevated temperature properties, also offers high resistance to erosion.

Type D-3A is recommended for use where a high degree of wear and galling resistance is required along with intermediate thermal expansion.

Type D-4 is superior to type D-2 or D-3 in resisting corrosion, erosion and oxidation.

Type D-5 is used whenever minimum thermal expansion is desired. It can also be preferred over other types of Ni-Resists to reduce thermal stresses.

Type D-5B is recommended for applications requiring a very low order of thermal stress. In addition, this type has a high

level of heat and oxidation resistance as well as good mechanical properties at elevated temperatures.

Type D-5S is recommended where oxidation resistance in air to 980° C is desired. It also resists embrittlement and offers thermal stability and strength in cyclic heating to 870° C.

(i) HEAT TREATMENT

To relieve residual casting and machining stresses Ni-Resist ductile castings are annealed at 620-675° C.

Annealing at 950-1040° C followed by uniform air cooling, or furnace cooling if preferred, will decrease the hardness to about 180 BHN or less while increasing elongation. Obviously the best results are obtained when the carbides have become completely spheroidized, which useally indicates that the minimum hardness has been reached.

(ii) WEAR AND GALLING RESISTANCE

The presence of dispersed graphite, as well as the work-hardening character of ductile Ni-Resist castings, provide a high level of resistance to frictional wear and galling. Type D-2, D-2C, D-3A and D-4 offer good wear properties with a wide variety of other metals and at temperatures from sub-zero to 815° C.

Ductile Ni-Resist castings provide excellent service where resistance to erosion and corrosion are required. For handling wet steam, salt slurries and relatively high velocity corrosive liquids, all of the types containing higher chromium levels, such as Types D-2B and D-3, have shown superior service.

(iii) CORROSION RESISTANCE

Corrosion properties of the ductile Ni-Resist alloys are comparable to those of conventional Ni-Resist. It is desirable to have two or more per cent of Cr present in the material for exposure in most corrosive media.

The Cr-Containing ductile Ni-Resists (D-2, D-2B, D-3, D-4 and D-5B) provide resistance to oxidation and maintain satisfactory mechanical properties to about 760° C. As such, they can be specified for applications including furnace parts, turbochargers and gas turbine parts. Table 1.7 [INCO (I3)] shows various commercial applications of the ductile Ni-Resist irons.

1.4 CONCLUSIONS

Starting from the basics, an effort has been made to highlight how the two broad categories of cast irons (white and grey) emerged as a consequence of differing solidification histories. Main stress has been laid on the development of

different grades of grey irons culminating in the design and development of the high alloy grades. The discussion also touches upon compacted graphite irons.

As the main thrust of the work is on white irons, the next chapter deals with unalloyed and alloyed white irons.

CHAPTER II

WHITE CAST IRONS

2.1 INTRODUCTION

White cast irons are so referred due to their characteristic silvery white fracture resulting from the absence of free graphite in the microstructure [Metals Hand Book, (M9), (M10), Charles (C2)]. The carbon is present in the form of massive carbides [Metals Hand Book (M9)]. These irons are hard, brittle and difficult to machine and therefore did not attract attention of metallurgists and materials engineers, as an engineering material for many years. In fact researching into white irons was not given credence and more than 90 per cent of total white irons produced was utilized in producing malleable iron castings. However, due to the possibility of exercising a closer control over the metallurgy and chemistry of the melts, a more efficient use of alloying element(s) along with appropriate inputs of heat treatment in improving properties, a better understanding of phenomenon occurring during service, improved testing facilities and availability of reliable experimental data interrelating theory with practice, have brought about a sea-change in this attitude. Economic aspects have contributed in no small a measure in giving a phillip to the R&D activities in

white irons. To sustain this interest, it would be relevant to critically examine the physical metallurgical thinking that has gone into the development of white irons in general and alloy white irons in particular. The following sections deal with this aspect.

2.2 PLAIN CARBON WHITE IRONS

Unalloyed white cast irons are metastable alloys of iron and carbon. A basic understanding of their behaviour stems from a study of the iron-iron carbide equilibrium [Charles (C2)].

The formation of cementite in place of graphite leads to a lowering in free energy but kinetically the formation of iron carbide is more probable [Lakhtin (L4)]. On the basis of metastable equilibrium (Fe-Fe$_3$C) diagram, the formation of different microconstituents on cooling is now well understood. For a hypoeutectic composition (most of the white irons are hypoeutectic alloys), the microstructure comprising cementite and pearlite resembles that of hypereutectoid steel except that the proportion of cementite is larger. Hypereutectic compositions contain undesirable free Fe$_3$C plates. The overall hardness of such a white iron (pearlite + cementite) lies in

the range of 400-600 VHN, the microhardness of the constituents being 200-300 and 800-1100 VHN respectively [Pearce (P11)].

Hardness can be controlled by controlling the proportion of these constituents through a control of carbon content/carbon equivalent [Rollason (R8), Angus (A2), Heine (H5)]. For most applications, a carbon content ≈ 3% is considered as an optimum.

White irons exhibit high hardness due to a continuous interdentritic network of cementite. This imparts excellent wear resistance although machinability is adversely affected. Therefore engineering applications of these materials are based on this single attribute (high hardness) as utilized in liners for cement mixers, ball mills, certain types of drawing dies and extrusion nozzles [Rollason (R8)].

Hardness of white cast irons increases with an increase in carbon content. This is explained on the basis of an increase in the proportion of the ledeburitic carbide. An unalloyed white cast iron containing 2.5 per cent carbon has a hardness of about 375 VHN which increases to ≈ 500 VHN on raising the carbon content to ≈ 3.5 per cent. The simplest method to attain a high resistance to wear is by increasing the 'C' content. In high carbon white irons, silicon is kept low. Taking an overall view,

the normal range of carbon content in unalloyed versions is 2.2 to 3.6 per cent. The hardness of a white cast iron can also be increased further by the substitution of the pearlitic matrix by a tempered martensitic one. In plain carbon white irons, a martensitic matrix can only be obtained in thinner sections with a drastic quench from the austenitic region. Such a treatment although likely to produce cracks is not effective in generating a martensitic matrix in thick sections in absence of alloying elements .

The carbon equivalent of white cast irons is so adjusted that for a given cooling rate, graphite is not formed during solidification. This effect is achieved by maintaining a high carbon to silicon (C/Si) ratio. The silicon content of white cast irons ranges from 0.3 to 1.2 per cent. Increasing the Si content lowers the carbon content of the eutectic and steadily loweres the eutectic temperature (Fig.2.1) [Minkoff (M13)]. A convenient way of representing the influence of silicon on the different structures in Fe-C-Si alloys is through a diagram which incorporates the effect of cooling rate and C/Si ratio on the microstructure. This is designated as the Maurer diagram (Fig. 2.2) [Rollason (R9)]. It in fact serves as the basis for designing plain carbon white iron compositions. The

favourable effect of a high C/Si ratio in ensuring the formatiorn of a white iron structure can be further accentuated by employing chilling. However, there are practical limitations to doing so. Representative compositions, properties and applications of plain carbon white irons are summarized in Table 2.1 [Angus (A2), Metals Hand Book (M11), Patwardhan (P10)].

Figure 2.3 [Metals Hand Book (M9)] shows Fe-C-2%Si system. The system is of particular interest as most of the white irons have a silicon content less than 2 per cent. The well defined sharply delineated eutectic and eutectoid temperatures, exhibited by Fe-Fe$_3$C system, change into a temperature regime by the addition of silicon. The eutectic and eutectoid points are also shifted towards lower carbon contents. Silicon, in this amount, is soluble both in ferrite and austenite and therefore the composition of carbide phase remains unaltered [Metals Hand Book (M9)].

2.2.1 APPLICATIONS

The applications of white irons as a wear resistant material dates back to over hundred years. Higher carbon lower silicon irons were developed for use specifically as wear resistant castings and are in use even today. The main limitation of these irons is their extreme brittleness coupled with poor toughness

and shock resistance. This tendency can be improved upon to some extent by restricting phosphorus to a low (<0.1%) level and also by adjusting carbon content to ≤ 3%. Toughness can be further improved by the addition of chromium up to 0.5 per cent [Durman (D9)]. This enables a graphite free structure to be achieved in thicker sections. The main advantages of unalloyed white irons are their relatively low price and, to a lesser extent, the fact that they can be melted in cupola [Durman (D9)].

The main advantage with unalloyed white irons is their low cost. One such example is associated with wet grinding (signifying a high rate of metal removal) wherein there is little economic justification to using alloyed cast iron grinding balls. In such instances where a wear rate of over 1 kg of balls per tonne of product ground is not unusual, high 'C' forged steel and unalloyed white irons find wide applications [Durman (D9)].

2.3 ALLOY WHITE CAST IRONS

Unalloyed and low alloy white irons attain a microstructure comprising a continuous and massive ledeburitic carbide (Fe_3C) in a predominantly pearlitic matrix. Due to their extreme brittleness, they have been largely replaced by the more tougher alloyed white irons. With an ever increasing use of materials in

applications involving resistance to wear, the major developmental efforts in alloyed white irons have centred around this application.

An important class of alloy white irons was developed by The International Nickel Company, Inc. (INCO) is known by their proprietary name 'Ni-Hard' irons. This class of materials represent an improvement over unalloyed white irons and owe their superior properties to the presence of nickel and chromium. Their microstructures essentially comprise iron-chromium carbides in a predominantly martensitic matrix.

Alloy white irons other than Ni-Hard irons are referred to as chromium irons or more precisely high chromium irons. These special purpose grades which have numerous applications contain chromium ranging from 12 to 30 per cent. Additionally, they frequently contain elements such as molybdenum and copper which are useful in enhancing the performance of these materials.

Manganese, which was rarely employed in developing cast irons, is now being extensively used and development of Cr-Mn cast irons has received major attention during the last decade. These efforts have reached a stage such that commercialization is a definite possibility .

2.3.1 NICKEL-CHROMIUM WHITE IRONS

These alloys are available in four different grades-the lower alloy versions designated as Ni-Hard 1,2 and 3 and their higher alloy counterpart Ni-Hard 4. Their chemical composition and the corresponding mechanical properties have been indicated in Table 2.2 [Patwardhan (P10), Inco (I1)].

When added to low chromium white iron [Metals Hand Book (M10)] in amounts up to about 2.5%, nickel produces a harder and finer pearlite in the structure, which improves its abrasion resistance. Nickel in somewhat larger amounts up to about 4.5% is needed to completely suppress pearlite formation , thereby ensuring that a martensitic iron results when the castings cool in their moulds. This latter practice forms the basis for production of the Ni-Hard cast irons (which are usually identified in standard specifications as nickel- chromium martensitic irons). With small castings such as grinding balls, which can be shaken out of the moulds while still hot, air cooling from the shake out temperature will produce the desired martensitic structure even when the nickel content is as low as 2.7%. On the other hand, an excessively high nickel content (more than about 6.5%) will so stabilize the austenite that little martensite, if any, can be formed in castings of any size.

Appreciable amounts of retained austenite in Ni-Hard cast irons can be transformed to martensite by refrigerating the castings at -55 to -75°C, or by the use of special tempering treatments [Metals Hand Book (M10)].

Ni-Hard cast irons are essentially Ni-Cr cast irons possessing outstanding resistance to wear. These irons in the mould cooled condition attain a matrix microstructure akin to that of heat treated steels. In addition they contain a multitude of refined carbides which make an important contribution to their abrasion wear resistance [INCO (I1)]. Chromium is useful in attaining a white iron structure and in hardening (and therefore strenghens through martensite formation) whereas nickel enhances hardenability and is useful in rendering carbides discontinuous through its graphitizing tendency.

Ni-Hard types 1 and 2 which contain relatively lower amounts of nickel and chromium were primarily developed as higher hardness and improved wear resisting materials, their fundamental property being high hardness. Microstructurally they comprise bainite/tempered martensite plus carbide [INCO (I1), Boyes (B12)]. An important observation concerning Ni-Hard 1 and 2 is that their shock resistance in general is low. However, the

shock resistance of Ni-Hard irons particularly of the low carbon and heat treated varieties is substantially better than unalloyed white cast irons. Ni-Hard 1 is used in applications where abrasion resistance is of prime consideration. For this, the carbon content is maintained in the range 3.2-3.6 per cent. However, if impact loading is involved, it is usual to restrict the carbon to $\approx$ 2.7-3.2 per cent (Ni-Hard 2).

The main drawback (poor shock resistance due to the presrnce of massive and continuous eutectic carbide network) of Ni-Hard type 1 limits its use in larger diameter grinding mills as liners or balls. It is still true ,but to a less extent , for Ni-Hard type 2 with low carbon content. For this reason , low carbon Ni - Hard type 3 was developed.Due to its much lower carbon content(Table 2.2) it has lower hardness but higher impact strength. In fact, Ni-Hard type 3 is a high carbon steel and is being replaced by Ni-Hard type 4 in many applications.

A modified version of Ni-Hard 1 and 2 containing higher proportions of nickel and chromium and designated as Ni-Hard 4 was developed by INCO around the mid-fifties [INCO(I1), Boyes(B12)]. The chemical composition and properties of Ni-Hard type 4 are summarized in Table 2.2. Important changes brought about in the composition of the type 4 namely 5 to 7% Ni in place

24671I.

of 5.5 to 6.5%, 7 to 11% Cr as against 7 to9% and 1.3% Mn (maximum) in place of 0.4 to 0.7% as per the recent literature published by INCO are noteworthy. The main objective in doing so was to improve the resistance to fracture under repeated impact. In view of a higher alloy content, the Ni-Hard type 4 variety is harder and has a greater resistance to corrosion. In fact Ni-Hard type 4 possesses the highest strength and greatest resistance to impact amongst the different grades of Ni-Hard irons. The advantage of a lower carbon content coupled with a somewhat tough high nickel matrix makes Ni-Hard 4 a very useful abrasion resistant material.

Besides the standard compositions described as Ni-Hard, a number of other nickel-chromium white iron compositions are also in use. Their representative compositions, properties and applications are summarised in Table 2.3 [Angus(A2), Metals Hand Book (M11), Patwardhan (P10)].

2.3.1.1 MORPHOLOGY OF CARBIDES IN NI-HARD IRON

The morphology of eutectic carbides is identical in Ni-Hard type 1,2 and 3. These irons display a quasi-regular eutectic structure with the major phase being the massive continuous M3C carbide. But the type 1 alloy is inferior to the rest in respect of shock resistance on account of its maximum carbon content. The
difference in the eutectic structure in type 1 and 4 irons may be explained by the pseudo- binary phase diagrams (Figure 2.4) [Chakraborty (C1)].

Carbide contents in type 1 are about 50 per cent and that in type 4 are 31 per cent (Figure 2.4), the latter being discontinuous and plate-like eutectic type. Through intensive investigations involving special etching technique it is opined that if an eutectic comprises constituents in equal amounts, they are continuous in three dimensions. However, if they are in unequal amounts, the minor phase will be discontinuous and embedded in the major phase. Applying this observation, it was inferred that in the type 4 alloy, the minor phase (carbide) will be discontinuous and embedded in the major phase (austenite) just after solidification [Chakraborthy (C1)]. Carbides are further rendered discontinuous in type 4 through a heat treatment comprising heating to the austenitic state , holding, to be followed by air cooling. This flexibility is not available in the lower alloy grades 1 to 3 as there is a danger of graphitization occurring during heat treatment.

2.3.1.2 NI-HARD 4 VS NI-HARD 1 AND 2 IRONS

Fracture in Ni-Hard type 1 and 2 castings normally results from the initiation and propagation of a crack in the continuous

brittle carbide . The susceptibility to failure by this mechanism is considerably reduced in Ni-Hard type 4 as the carbides [trigonal $(Cr,Fe)_7C_3$] are discontinuous and in a less massive form due to the modified composition. In fact for all practical purposes the carbides are regarded as discontinuous. As already stated, heat treatment may prove additionally beneficial. Similarly, controlled quantities of austenite present in the type-4 alloy can be used to advantage in blunting crack propagation.

Until recently, the increased toughness and better resistance to fracture of Ni-Hard type 4 and other high chromium irons was attributed to the presence of discontinuous carbide as described in the preceeding paragraphs. According to Powell [Powell (P14)] the term "discontinuous" is misleading and both eutectic phases are continuous. The difference in mechanical properties of Ni-Hard type 1 and 2 and Ni-Hard type 4 is due to different types of anomalous eutectic structures. Powell could not assign any reason for the similarity in morphology of the carbide in type 4 and that of carbide in high chromium irons (27 per cent chromium and 17 per cent chromium - 1.5 per cent molybdenum white irons) but explained that eutectic carbide (M_7C_3) in Ni-Hard type 4 comprises of blades and hollow rods of hexagonal cross-section. This carbide is not discontinuous in

three dimensions and is continuous as rods and blades. This structure is akin to that of composites (hard carbide being present in the softer austenite) and therefore exibits better toughness compared with that attained in Ni-Hard 1 and 2.

2.3.1.3 HEAT TREATMENT OF NI-HARD IRONS

Practically, all Ni-Hard castings are heat treated before being used in service. Heat treatment of these castings enhances impact resistance and reduces stresses in the casting.

Ni-Hard type 1,2 and 3 are subjected to two main types of heat treatments i.e. (i) single heat treatment : tempering at 275°C for 4 to 16 hours followed by air cooling and (ii) double heat treatment : (a) tempering at 450°C for 4 hours followed by air cooling/furnace cooling to 275°C, (b) tempering at 275°C for 4 to 16 hours followed by air cooling. For Ni-Hard type 4 iron, any one out of following heat reatments is employed.

(i)   8 hours soaking at 750°C followed by air cooling.

(ii)   4 hours soaking at 750°C followed by air cooling. Again 4 hours soaking at 75°C followed by air cooling.

(iii) 4 hours at 550°C, air cooled and 16 hours at 450°C, air cooled.

These heat treatments result in considerable improvement in strength and impact resistance (sometimes by 50 to 80 per cent or more). It is accomplished without any loss in hardness or abrasion resistance [INCO (I1)].

2.3.1.4 APPLICATIONS OF NI-HARD IRONS

Ni-Hard irons are famous for their outstanding resistance to wear. Their use in the mining, power, cement, ceramic, paint, dredging, coal, coke, steel and foundry industries is now well established as an outcome of the experience gained over nearly fifty years. Typical applications include rolling mill rolls, grinding media balls, grinding mill liners, slurry pump parts, pulverizer rings, roll heads, pipe and elbows; and mixer blades etc [Patwardhan (P10)].

Ni-Hard iron castings have demonstrated oustanding ability to resist abrasion at temperatures upto red heat. Sand cast Ni-Hard which possess a hardness level of 600 BHN at room temperature maintains a hardness of approximately 475 BHN at 480°C. This accounts for its ability to resist abrasive and metal-to-metal wear even at elevated temperatures. Ni-Hard can be considered for service at temperatures upto 815°C as long as operating conditions do not involve severely rapid or localized heating and cooling [INCO (I1)]. Ni-Hard liner plates and flight

segments can successfully resist the abrasion of cement clinker at temperatures up to 815°C [INCO (I1)].

2.3.2 CHROMIUM IRONS

Chromium, by virtue of being a strong carbide former markedly influences the behaviour of cast irons and when present in large amounts , imparts outstanding wear, corrosion and heat resistance [Ohide (O1)]. The range of chromium contents used in high chromium irons varies from 12 to 30 per cent. Presence of chromium in large amounts alters different phase fields, the stability of phases and the eutectic temperature and composition. The precise nature of change will depend upon the chromium and carbon contents and whether or not other elements are added e.g. the nature of the matrix could vary from ferrite to austenite [Barton (B4)]. An equally important effect is the formation of stable Cr- carbide in preference to iron carbide (Fe_3C).

There are two main reasons for the success of high chromium irons. Firstly, the modification of the iron-carbon solidification process at approximately 12% chronium leading to the formation of chromium carbides (Cr_7C_3) in place of cementite (Fe_3C). The chromium carbides are harder than cementite and thus improve wear resistance. Further, they tend to be far more

compact and do not form the cellular eutectic structure characteristic of unalloyed white and martenstic irons. This leads to a significant improvement in toughness [Durman (D9)]. Secondly, the matrix microstructure of high chromium irons can be altered from a fully heat treated martenstic matrix to a completely austenitic work-hardenable matrix so as to cater to differing end requirements.

Depending upon the chromium content, the high chromium irons may be divided for practical purposes into three groups [Barton (B3)];

(i)   15-17% Cr for heat and wear resistance applications.

(ii)   26-28% Cr for abraion resistance applications

(iii) 30-35 Cr for heat and corrosion resistance applications.

Typical compositions and properties of some representative (abrasion and wear resistant) chromium irons are shown in Table 2.4 [Angus (A2),Patwardhan (P10)]. Table 2.5 [Angus (A2), Metals Hand Book (M11), Patwardhan (P10)] summarizes information on chromium irons used for corrosion resistant applications.

The principal effect of carbon in chromium irons is to form carbides and since it also controls the amount of eutectic carbon present, the carbon content is important in determining the

hardness of the material. It is usually found that as the eutectic carbon content is approached, the fineness of carbides increases resulting in improved strength. When the carbon content exceeds the eutectic concentration coarse carbides appear which have a deleterious effect on the properties [Barton (B3)].

For applications demanding maximum heat and corrosion resistance, the bulk of the chromium present should be in solution in the matrix. It is usual to limit the carbon to 1.2-1.8 per cent. However, for attaining a high resistance to abrasion, the carbon content is controlled around 2.7-2.8 per cent which in combination with 27-28 per cent chromium gives an iron of eutectic composition [Barton (B3)].

2.3.2.1 CARBIDE MORPHOLOGY IN CHROMIUM IRONS

The as-cast microstructue of high chromium irons consists principally of eutectic carbides in a chromium-rich ferritic matrix. Between about 5 and 10 per cent chromium, the dominant carbide is the $(FeCr)_3C$ which has a needle-like morphology, is coarse and primarily responsible for the extremely high hardness. More recent work [Torpe (T1)] suggests that at $\approx$ 8-10% Cr, the eutectic carbide is of a duplex type comprising an inner core of M_7C_3 and an outer shell of M_3C formed during cooling within the solid state. It is possible that the $(Cr,Fe)_7C_3$ is the first

carbide to form by a reaction similar to the eutectic reaction observed in the high chromium irons and controls the subsequent growth of the (FeCr)$_3$C carbide from the melt either by a peritectic or by an eutectic transformation. It is believed that these carbides constitute the matrix [Torpe (T1)].

Three dimensional studies carried out on M$_7$C$_3$ carbides by Powell [Powell (P14)] suggest that the true carbide morphology is fibrous, the fibres being hexagonal in cross section with adjacent fibers frequently attached together to form blades. The high hardness ($\approx$ 1600 HV) of this carbide and its relatively 'enhanced discontinuity' within the eutectic colony result in an optimum resistance against wear and impact.

However, at chromium contents in excess of 10 per cent, eutectic carbides of the type M$_7$C$_3$ are formed in preference to the M$_3$C. More significantly, the increased chromium content causes a change in the solidification pattern such that the M$_7$C$_3$ carbides are surrounded by a matrix of austenite/its transformation products. This difference in the solidification characteristics makes the hypoeutectic irons containing M$_7$C$_3$ carbides more stronger and tougher than irons containing M$_3$C carbides. Information on different carbides observed in Fe-C-Cr system and their possible impact on properties is summarized in

the Table 2.6 [Ohide (O1), Goldschmidt (G2), Metals Hand Book (M10)].

The high chromium irons [Sare (S3)] are most frequently used in the heat treated condition, in which the austenitic as-cast matrix is rendered less stable by the precipitation of secondary carbides at high temperatures so as to enable its transformation to martensite on cooling. However, some alloys, namely the 27% Cr white irons, are frequently used in the austenitic condtion to utilize the amenability of the matrix to work hardening (as in Hadfield steels) even though the service conditions may not entail severe impact loading.

From an application point of view the chromium white irons can be grouped into three classes namely wear resistant, heat resistant and corrosion resistant irons. The following sections are devoted to a critical reappraisal of these varieties.

2.3.2.2 WEAR RESISTANT CHROMIUM IRONS

High chromium cast irons effectively resist different forms of wear encountered in crushing and grinding of ores, coal and cement- pulverising materials. Wear resistance is controlled by hardness of the carbide and the type of matrix present. A detailed analysis of the effect of metallurgical parameters in

influencing the wear behaviour of alloyed white irons has been putforth by Singh and Patwardhan [Patwardhan (P10)]. In the present context, a carbon/chromium ratio to yield an eutectic composition will produce the finest distribution of carbides and help attain an optimum balance between hardnes and toughness. In the as-cast state the matrix of the high chromium irons is ferrite although Hughes and Monaghan [Hughes (H12)] state that some austenite is also present. It is generally agreed that a matrix comprising unstable or 'transformable' austenite is most suitable for attaining a high wear resistance and this can be effectively attained in high chromium irons through heat treatment. Hughes et al [Hughes (H12)] have also shown that if pure sliding wear is experienced, a fully hardened martnesitiic matrix is most useful.

Generally, abrasion resistance increases with an increase in material hardness, which in turn is influenced by microstructural features such as the volume fraction of carbides, its morphology and the structure of the matrix.

On the other hand, as the toughness of cast irons is also affected by microstructure, high chromium cast irons, which contain discontinuous eutectic carbides of the type M_7C_3 , have a higher toughness than low alloyed white irons attaining

continuous M$_3$C carbides. It is therefore expected that control of the shape, size and distribution of eutectic carbides should not only improve their toughness but also the abrasion resistance.

The carbides in the microstructure, depending upon their type, morphology and volume fraction, provide the hardness required for crushing materials without degradation. The supporting matrix microstructure, which controls the abrasion and crack propagation characteristics, can be controlled by alloy content and/or heat treatment to develop pearlitic, austenitic or martensitic structures to provide the most cost effective balance between abrasive wear resistance and toughness [Elliott (E2)].

The complex dependence of wear on microstructure is illustrated in a recent study on the grinding abrasion resistance of chromium irons in the as-cast and heat treated conditions [Pearce (P12)]. A martensitic matrix displayed higher abrasion resistance than austenitic or pearlitic matrix structures. The 10-15% chromium irons were more resistant than 25-30% chromium irons due to the low carbon martensite produced on reducing the stability of the higher chromium irons. The 5% chromium irons exhibited a good wear resistance than the 10-15% chromium irons. This was because cracking in the carbide phase did not lead to its immediate removal from the structure due to the 'continuous'

structure of the carbide as in the 5% chromium irons. On the other hand the fractured carbide rods in the 'discontinuous' eutectic in the 15% chromium irons became detached readily during wear.

These findings differed when impact loading accompanied wear. Under these conditons, structures with continuous carbides showed insufficient toughness and suffered gross fracture. However, a microstructure with a discontinuous eutectic withstood impact loading effectively and gross failure was avoided at the expense of greater wear, particularly if the carbide is not adequately supported by a hard matrix.

For counteracting high stress abrasion there is the feasibility of attaining a tough austenitic matrix to room temperature through controlled solidification, forming a self replacing hard case while retaining a comparatively softer core. In applications where metal- to-metal contact is insufficient to result in work hardening, or under conditions of severe repeated impact when the development of internal stresses is a problem, high chromium irons can be heat- treated to provide a hard martensitic structure throughout the cross- section [Durman (D9)].

Lining plates, grinding balls and auxiliary castings for the attrition of various materials in tubular ball mills is probably the largest single application of chromium white irons. High carbon high chromium castings are generally employed as lining plates. . In instances involving very high impact or where exceptionally large sized alloyed balls are used, the lower carbon heat treated versions are used. High chromium iron grinding balls are manufactured and used in all sizes, although it is important to use a composition suitable for a specific application. Higher carbon irons are generally used for small diameter balls and the lower carbon compositions in the heat treated conditions are more suitable for larger sized balls [Durman (D9)].

High chromium irons have also met with a major success in the cement industry. The requirement of good toughness associated with high wear resistance against a highly abrasive product, is achieved with ease in a series of low carbon high chromium heat treated white irons [Durman (D9)].

High chromium cast irons have been well-known for their abrasive wear resistance. Typical applications are materials such as balls, liners, rollers, rings for pulverizer mills, impeller

blades for shotblast equipment and impact crushers, dredge pump parts and wearing parts for steel making plants [Matsuraba (M7)].

2.3.2.3 HEAT RESISTANT CHROMIUM IRONS

The scale on pure iron consists of three layers : an outer one of Fe_2O_3; an intermediate one of Fe_3O_4; and an inner one of FeO. Scale on cast irons is more adherent than on steels and hinders free access of the atmosphere to the metal below, so that attack is reduced unless the scale is cracked or removed mechanically. Scale is usually continuous and adherent at least up to 800°C. It is usual to assess the heat resistance of cast irons by exposing them to air at a given temperature for a given period of time and by assessing how effectively they are able to resist such an exposure.

The excellent heat resistance of the high chromium irons is due to the formation of an adherent oxide scale which reduces further progressive oxidation to a minimum, and also to the stability of the iron-chromium carbides which do not break down on exposure to high temperatures. The work of Burgess [Burgess (B13)] suggests that a 12 per cent chromium iron is satisfactory up to 840-850°C, a 15-17 per cent chromium iron up to 900°C, 25 per cent chromium upto 980°C and a 33 per cent chromium iron upto

1050°C. Hallett [Hallett (H1)] has confirmed the excellent growth and scaling resistance of the high chromium irons.

High chromium white irons affer excelllent resistance to growth and oxidation at elevated temperatures and are cost effective alternatives to staineless steels in applications that are not subjected to severe impact loading [Elliott (E2)].

For developing resistance to the softening effect of heat, and for protection against oxidation, chromium is the most effective element. It stablizes iron carbide and therefore prevents breakdown of carbides at elevated temperatures. 1% chromium gives adequate protection against oxidation up to about 750°C in many applications. For temperatures above 750°C, the chromium content should be greater than 15% for long-term protection. This percentage of chromium suppresses the formation of graphite and makes the alloy solidify as white cast iron [Boyes (B12)].

Chromium cast irons have better mechanical properties than those of high silicon irons and respond better to heat [Metals Hand Book (M10)].

It may be noted that no research on the heat-resisting properties of high chromium irons has been done since the

detailed investigations made by Corti et al [Corti (C3)]. The literature published by Climax-Molybdenum Co. is not readily available.

2.3.2.4 CORROSION RESISTANT CHROMIUM IRONS

High chromium white irons have useful corrosion and heat-resisting properties but there has been little recent research on these materials. In fact, limited data are available on their corrosion resistance in some environment. Patwardhan and co-workers [Patwardhan (P2)], working in this area since last several years, are now in a position to predict corrosion behaviour of alloyed white irons based on models interrelating corrosion rate with the microstructure. Dodd [Dodd (D2), (D3)] has reviewed corrosion characteristics of chromium white irons and pointed out that irons containing 0.5-2.0 per cent carbon and 20-28 per cent chromium offer a useful compromise between resistance to corrosion and to abrasion.

High chromium irons owe their excellent corrosion resistance to the presence of an impervious and highly tenacious surface film of chromium oxide. In a particular corrosive medium, the corrosion behaviour would depend upon whether the film is formed or repaired more rapidly than it is broken down. Since the corrosion resistance of the alloy is basically due to the oxide

film, oxidising agents/atmospheres maintain the oxide film while reducing conditions give rise to rapid attack [Barton (B3)].

To ensure maximum corrosion resistnace, the chromium content should exceed the amount required to form carbides by atleast 10 per cent. An increase in the silicon content further increases the corrosion resistance by refining carbides. This leads to the development of a more continuous oxide film over the metal surface. Addition of molybdenum has a similar effect. It may enhance corrosioin resistance by displacing some chromium by combining with carbon, thereby increasing the chromium content of ferrite [Barton (B3)].

High chromium irons resist nitric acid well. Corrosion rates in this medium are less than 5 mil/year at all temperatures up to the boiling point and in concentrations upto 70 per cent. However boiling concentrated nitric acid is very corrosive to high chromium irons. No reliable information is available on the behaviour of these irons in sulphuric acid. Similarly not much is known about the response to hydrochloric acid; apparently the concentration would be the deciding factor. The high chromium cast irons have a useful resistance to sulphurous acid in all concentrations up to 80°C.

As regards the organic acids, high chromium cast irons offer excellent resistance to acetic acid at all temperatures and concentrations. The corrosion rate in this medium is less than 5 mil/year. However, the poorer resistance to formic acid is essentially due to its reducing nature. Even then, exposure of a 10 per cent solution at 20°C and the 100 per cent acid at all temperatures upto boiling point, result in corrosion rates of less than 5 mil/year. These irons exhibit good resistance to lactic and citric acids in dilute solutions.

High chromium irons offer no useful resistance to alkalis. In the absence of solid deposits or crevice effects, high chromium cast irons are practically immune to corrosion by aerated sea-water and most mine waters. In fact, these irons are most suitable for pumping acid mine waters.

High chromium irons show oustanding resistnace to atmospheric corrosion. It is claimed that the iron containing about 34 per cent chromium and 1.1 per cent carbon do not rust when exposed to the atmosphere in the as-cast state. A similar alloy containing 2.3 per cent carbon is stated to be only slightly inferior in this regard, but on increasing the carbon to 3.1 per cent, a marked rust film develops. However, in the

machined   and   polished state, all these alloys were found to be
fully resistant i.e. stainless.

Increasing use is being made of high chromium cast irons
[Corti (C3), Boyes (B11)] for applications at high temperatures
as well as moderate   to high temperatures where their high
resistance to abrasion, wear and corrosion is well known.
Besides their excellent corrosion resistance, these irons can be
centrifugally cast as tubes and   are inexpensive compared to
wrought high alloy steels despite their high chromium content.

These   irons   are   most   usefully used in environment
containing a plentiful supply of oxygen or oxidising agents.
Anearobic or reducing conditions would lead to rapid corrosion.
Low carbon versions are useful for annealing pots, lead, zinc or
aluminium melting pots, conveyor links and other parts exposed to
corrosion at high temperature. An important area of application
is when high temperatures (upto 1000°C) are encountered [Metals
Hand Book (M10)].

2.3.3 CHROMIUM-MOLYBDENUM IRONS

Massive castings, with section sizes of the order of 250 mm
or larger and weighing several tonnes, are being utilized as mill
liners, pulverizer rolls, slurry-pump impellers and rolling mill

rolls. Abrasive wear and failure by spalling or fracture are the limiting factors in the performance and reliability of these thick-section castings. Large tonnage of high chromium-molybdenum irons are currently being produced for thick-section castings which require a combination of abrasive wear resistance and toughness not obtainable in other alloyed irons or steels.

High chromium irons , in general, contain hard, relatively discontinuous M_7C_3 primary or eutectic carbides or both. Molybdenum is soluable in M_7C_3 carbides, and significant amount of molybdenum partition to the M_7C_3 phase. Molybdenum-rich M_2C eutectic carbides and M_6C carbides have been observed in high Cr-Mo irons. Manganese also has similar tendency as that of molybdenum. The alloying elements namely silicon, nickel and copper have limited solubility in the carbide phases and, therefore, are concentrated in the metallic matrix.

The as-cast matrix microstructure (in thin sections) is predominantly austenite with a very small amount of pearlite and some martensite adjacent to the eutectic carbides. The microstructure in thick-sections comprises a larger proportion of martensite and secondary carbides precipitated in the centre of the austenite dendrites.

The microstructures of heat treated thick-section castings are similar in nature to those in thin-sections. The heat treatment consists of heating to high temperature, usually in the range 950 to 1060°C and cooling (quenching) to obtain a martensitic matrix. Such heat-treated high Cr-Mo irons show the best combination of abrasion resistance and toughness, particularly resistant to spalling and fracture under conditions of severe repeated impact.

However, cast irons (Cr-Mo ones) with either austenitic or austenitic-martensitic matrix microstructures have been used successfully for castings which do not encounter severe impact in service. The most obvious advantage of using high Cr-Mo irons in the as-cast condition is the cost savings and energy conservation that results from eliminating the high temperature heat treatment.

The as-cast Cr-Mo irons during mould cooling as well as heat- treated irons cooled or quenched after reaustenitizing treatments may have ferrite-carbide constituents present in the matrix microstructure if hardenability is not properly controlled. Presence of ferrite- carbide constituents, even in small amounts, reduces the abrasion wear resistance. Since it is difficult to control cooling rates, specially of a thicker

section casting, the hardenability of Cr-Mo irons is usually controlled by adjusting the carbon and chromium contents. Another way is through alloying (Mo, Mn, Ni or Cu).

The addition of molybdenum to high chromium white irons suppresses the decomposition of autenitic matrix to form pearlite. Maratray and Usseglio-Nanot [Maratray (M6)] concluded that one- half of the molybdenum in the alloy forms the carbide (Mo_2C), one-fourth dissolves in the M_7C_3 carbide, and the remaining one- fourth remains in the matrix.

The high Cr-Mo irons currently produced generally have carbon contents in the range 2.4 to 3.0% and chromium contents in the range 18 to 22%. At these levels, the amount of eutectic carbide is large enough to ensure good abrasion resistance and adequate toughness, and the amount of chromium in the matrix makes a moderate contribution to hardenability.

High Cr-Mo irons are used for abrasion-resistant castings ranging in size from very small(12 mm) diameter grinding balls up to massive (335 mm) thick table segments for roller pulverizers.

The high Cr-Mo white cast irons [Frost (F1)] exhibit substantially improved toughness than the unalloyed white irons, high chromium irons, and high nickel martensitic irons mostly due

to improved carbide morphology and distribution. These alloys have stood to benefit from the superior abrasion resistance provided by the M_7C_3 chromium carbides in applications such as grinding balls and ball mill liner plates where high impact loading is observed.

A martensitic matrix may be obtained on heat treating Cr-Mo white irons by soaking for 4 hours at a temperature of 982°C, followed by an air cool. This heat treatment results in the precipitation of M_7C_3 carbides and a martensitic matrix on cooling. Dodd, et al, have shown that the martensitic transformation is not complete and up to 40% austenite may remain in the microstructure [Frost (F1), Dodd (D4), (D5)].

Compositions and properties of some Cr-Mo white cast irons are summarized in Tables 2.7 and 2.8 [Angus (A2), Patwardhan (P10), Metals Hand Book (M10)].

2.3.4 CHROMIUM-MANGANESE IRONS

Nickel is an expensive alloying element and so nickel bearing materials are costly. An attempt, to replace this costly element in Ni-Hard irons by a comparatively cheaper element manganese, has been recently tried in chromium cast irons [Tsypin (T2)]. Manganese can be used successfully to suppress the

pearlitic transformation in cast irons. Depending on the manganese content of the chromium-manganese cast irons, the matrix microstructure in the as-cast condition could be either a mixture of pearlite, austenite and martensite or fully austenitic. The carbide morphology of chromium-manganese white irons is similar to that of high chromium white irons (discontinuous M_7C_3 type).

Manganese, an efficient carbide stabilizer but a weak carbide former, partially joins the M_7C_3 carbides. Most of the reported literature on Cr-Mn cast irons deal with high chromium contents i.e. more than about 12% chromium except a few [Srinivasan (S12), Sudan (S17)] with lower chromium contents (about 7%). In these reports [Srinivasan (S12), Sudan (S17)] in addition to the effect of manganese, the effect of copper has also been studied. The as-cast structure comprises of retained austenite. This ratained austenite can be minimized by various heat treatments. Depending upon the service conditions, the alloys with austenitic matrix, obtained either in as- cast or heat treated condition, may exhibit very good performance specially in impact-abrasive wear appliations. In this case, the austenitic matrix gets strained due to impact and subsequently gets transformed probably into strain martensite [Rozhkove (R10)].

The microstructure [Stefanescu (S14)] of the 15% chromium white cast iron (without manganese) consists of pearlite and carbides of the $(Cr, Fe)_7C_3$ type. As the manganese content of the alloy increases, the pearlite/austenite ratio decreases and at 5% manganese (15% Cr-5% Mn cast iron) a matrix being mainly austenitic is obtained. The increase in manganese content also influences carbide morphology e.g. a large proportion of lamellar carbides are observed in a 15% Cr - 4.5% Mn cast iron at room temperature. With differential etching, two different types of carbides are observed : some with dark-grey colour and the others with light-grey colour. The dark carbides, revealed by Murakami etchant, are of the $(Cr, Fe)_7C_3$ type. They grew during eutectic solidification. The light-grey carbides also appear during eutectic solidification. The light- grey carbides are not present in the structure at lower manganese contents. From the microprobe examination, it was found that both carbides are chromium carbides. It was concluded that the diffference in colour is due to different chromiun contents, manganese partitioning being uniform enough [Stefanescu (S14)].

2.4 CONCLUSIONS

This chapter essentially dealt with the development of (i) unalloyed white irons and (ii) the proprietary alloy white irons

compositions namely the Ni-Hard and Cr-Mo cast irons already in use. The advantages and limitations of lower alloyed grades of Ni-Hard have been discussed. It is clearly brought out as to how these problems have been overcome through the development of Ni-Hard 4 irons.

A critique on the development of high Cr-irons revealed their apparent superiority over Ni-Hard irons. However, a more closer analysis and detailed experimentation is necessary to establish whether such a superiority really exists. An important variety of white irons excluded from the discussion are the Mn-Cr-Cu white irons. The physical metallurgical aspects related with their development leading to the formulation of the problem are discussed in the next chapter.

STUDIES IN THE Fe-Mn-Cr-Cu SYSTEM: FORMULATION OF THE PROBLEM

3.1 INTRODUCTION

A critical survey of the literature revealed that Ni-Cr and high Cr white irons (with or without Mo, the latter being more popular) are in extensive use for a wide range of applications. Whereas the major applications of the former, commonly known by their proprietory name NI-HARD, are as wear resistant materials (Ni-Hard 4 also shows excellent corrosion and high temperature resistance), the Cr-Mo/Cr-irons are well known for their excellent wear, heat and corrosion resistance.

The high cost and scarcity of the major alloying elements (Ni,Mo) in the abovesaid irons in the Indian context lead to an interest in developing low cost substitutes for Ni-Hard/Cr-Mo cast irons. Although the initial indigeneous attempts were aimed at substituting the scarce elements partly or fully, it soon emerged that developing substitutes was no more a local necessity in view of the high prices of metals in the International market. Based on fundamental considerations, it was surmised that Ni can be replaced either partially by Mn and Cu.

Manganese, like Ni is a complete austenite stabilizer and

therefore can be successfully employed to (i) refine pearlite and (ii) promote the formation of any desired matrix (eg. bainite/ martensite/austenite) in the as-cast condition. It has a mild carbide forming tendency [Bain (B1)]. The carbide morphology of Mn-bearing Chromium irons was found to be similar to that observed in high Cr-irons (i.e. M_7C_3 type) because Mn and Cr have a similar carbide forming. tendency [Stefanescu (S14), Basak (B6)]. In a nut shell Mn could effectively perform the functions of both Ni and Cr.

Cu cannot fully stabilise austenite because of its low stability in ferrite [Bain (B1)] and therefore for it to be effective the presence of another austenite stabilizer is essential. On the basis of a comparision between a 4Ni-2Cr and a 1.5Ni-2Cr-3Cu white irons, Henon [Henon (H6)] concluded that Ni-Cr-Cu irons could be used in place of Ni-Cr irons in a number of applications thereby substantiating the point mentioned above.

Going by the aforesaid favourable evidence and realizing the immense economic implications that lay in store, developmental efforts were initiated by Patwardhan in the early seventies [Patwardhan (P2)] with a view to develop low cost substitutes for Ni-Hard cast irons based on the utilization of indigenously available elements. Some of the early results based on the work

of Srinivasan [Srinivasan (S12)] later to be reported by Srinivasan, Patwardhan and Mehta [Srinivasan (S13)] revealed that Fe-Cr-Mn-Cu alloy white irons could attain microstructures similar to those observed in Ni-Cr white irons. However the carbides formed were massive and were rendered discontinuous only on heat treating from high temperatures (>850°C).

Work related to the optimization of copper and manganese was carried out by Sudan [Sudan (S17)] and Sharma [Sharma (S7)] respectively. Sudan, Patwardhan and Mehta [Sudan (S18)] while studying the effect of 0.5,1,2 and 3%Cu on the microstructure and hardness of a 7%Cr, 1.5%Si and 3.1%C cast iron, reported that hardness in excess of 650VHN could be attained only on quenching. However, copper was extremely effective in rendering the carbide network discontinuous. Taking an overall view, the optimum copper content appeared to be ≈1%.

Patwardhan, Mehta and Sharma [Patwardhan (P7)] while reporting on the possible effects of 2,4, and 6% Mn on the transformation behaviour of 7%Cr-1.5%Si-3.1C, observed that although Mn was extremely useful in attaining a high hardness (>650VHN) without the necessity of quenching, it was not effective in making the carbide network discontinous. The optimum Mn content was ≈4%.

Based on the above studies Patwardhan conceived that a composotion containing ≈4%Mn,≈1%Cu, ≈7%Cr and about 1.5%Si could be a useful alternative to Ni-Hard 4 cast iron and was investigated partly for the effect of heat treatment on the nature of microstructure. Through such a study Jha et.al [Jha (J11)] showed that microstructures and hardness similar to those attained in Ni-Hard are also attainable in the Fe-Mn-Cr-Cu alloys.

Around this time Patwardhan opined that two possible lines of approach existed. The first essentially comprised developing low cost wear resistant compositions. This line of approach was pursued by Singh [Singh (S10)] who examined a series of Fe-Mn-Cr-Cu alloys to arrive at optimum alloy composition(s) which could serve as low cost substitutes for Ni-Hard/Cr-Mo wear resistant cast irons.

The second line of approach comprised developing corrosion resistant microstructures by following the white iron route. The reasons for following this line of approach have been elaborated upon in the next section. This discussion would also highlight the advantages that will accrue and also summarise the salient results obtained. All these aspects formed the basis of formulating the present problem.

3.2 THE APPROACH

The present investigation was primarily undertaken to assess the feasibility of developing low cost corrosion resistant white irons. It was felt appropriate to undertake such a study as the backup information, as discussed above (Section 3.1), had revealed that the Fe-Mn-Cr-Cu system held promise.

A comprehensive review of literature on corrosion resistant alloy cast irons currently in use namely ferritic (high Si), austenitic (high Ni) and high Cr with or without Mo (ferritic/ martensitic/austenitic) revealed that the high Si irons are most usefully utilized under oxidising conditions [Shreir (S9), Kumar (K7), Jain (J3), (J4)]. Their poor mechanical strength and shock resistance preclude their general engineering applications [Shreir (S9)]. Ni-Resist irons although useful in a variety of environments, have a low strength and are unsuitable at service temperatures >800°C [Jain (J2), (J3), (J4); Kumar (K9)]. A major drawback with the high Ni and high Si irons is that they suffer from graphitic corrosion- a phenomenon that is highly undesirable. The higher Cr irons, which can develop all matrices and which should be essentially classified as wear resistant materials, can in principle be employed upto higher service temperatures owing to the presence of a large Cr

content. Their shock resistance is improved by lowering 'C' content [Metals Hand Book (M11)]. Dodd [Dodd (D2), (D3)] has demonstrated that irons containing 0.5-2.0% C and 20-28% Cr can offer a useful compromise between resistance to corrosion and abrasion. Nonavailability of published literature lead to a possible inference that not much effort has gone into the study of electrochemical and deformation behaviour of high Cr irons.

Realizing the above, Patwardhan propounded the idea that the development of corrosion resistant cast irons was feasible by following the 'white iron' route. He was encouraged in his belief by the realization that the difference in electrochemical potentials between austenite and carbide was lesser than that between austenite and graphite. A major advantage foreseen was the possible elimination of graphitic corrosion- a severe problem associated with high alloyed corrosion rasistant grey irons. Such a study was expected to become additionally meaningful if it were possible to develop alloys at a minimum of cost i.e. by utilizing low cost indigeneously available alloying elements. Patwardhan [Patwardhan (P2), Kumar (K9)] further opined that Fe-Mn-Cr-Cu white irons can be sucessfully developed to resist corrosion, wear and corrosive wear as the system provided flexibility in attaining different matrices (pearlite, bainite, martensite and austenite) through the use of relatively lower amounts of

alloying elements. The work done by Singh [Singh (S10)] and Basak et.al [Basak (B5)] proved useful in strengthening this belief.

This prompted Patwardhan [Patwardhan (P2)] to initiate an alloy development programme for developing low cost alternatives to the existing high nickel austenitic corrosion resistant cast irons. The idea thus propounded was investigated upon by Jain [Jain (J2)] in a study which dealt with the characterization of microstructures encountered in a series of Fe-Mn-Cr-Cu white irons, based on their electrochemical and deformation response. Major conclusions of design interest (Table 3.1) [Patwardhan (P4), (P5), (P6); Jain ((J5)] emerged, one of the highlights being the quantization of different correlations. On the basis of these relations, Jain and Patwardhan [Patwardhan (P4), (P5), (P6); Jain (J5)] were able to propose models interrelating microstructure with the transformation, corrosion and deformation behaviour. The data thus obtained proved helpful in designing future compositions to reach to the final objective.

The present investigation was accordingly undertaken in order to study the various microstructures encountered in low cost white iron compositions incorporating Mn, Cr and Cu as the main alloying elements and to correlate the effect of matrix/

microconstituent(s) with the hardness, deformation behaviour and resistance to corrosion. As would be clear, the alloys investigated differ in their composition significantly from those investigated by Jain. The compositions were to be so designed that the microstructures of interest could be attained at a minimum of alloying either in the as-cast condition or through simple heat treatment(s). It was decided to develop microstructures comprising austenite and carbide since single phase austenite was adjudged to be most effective in resisting corrosion. Additionally, austenite based microstructures can be made to respond favourably to work hardening, useful in imparting high resistance to wear and perhaps corrosion if the need so arose. It was decided to concentrate on optimizing second phase present in the form of massive and dispersed carbides. Priority was accorded to the possible elimination of dispersed carbides as they were found to adversely affect the corrosion resistance.

3.3 DESIGN OF ALLOYS

The Fe-Mn-Cr-Cu system was chosen for the present investigation in view of the following:

(i) Mn improves hardenability significantly at a low cost, helps in retaining austenite, stabilises carbide, and does not adversely effect fluidity.

(ii) Cu is a useful graphitizer (helpful in rendering carbides discontinuous and in altering carbide morphology during heat treatment), solution hardens and improves resistance to corrosion in the presence of dilute acids (acetic, sulphuric, hydrochloric) and acid mine waters.

(iii) Cr stabilizes carbide, is helpful in attaining a uniform microstructure (i.e. with a minimum of segregation) and may prove useful in attaining martensite/austenite even if present singly in large proportions.

Since the aim was to obtain an austenitic matrix and to assess whether it is necessary to aim for a near eutectic microstructure, the primary element i.e carbon was kept around 3.7%. A different carbon content was also selected in a parallel study [Rao (R3)] to arrive at the relevance or otherwise of adjusting the alloy composition close to the eutectic. Carbon, besides increasing fluidity, stabilizes austenite and enhances solubility of copper in cast irons. Silicon was controlled ≈1.5-2% - a range in which it is normally present in white cast irons. Chromium was restricted to ≈6%, in order to ensure that compositions were cast white. The amount was based on the data of Singh [Singh (S10)] which revealed that raising Cr level from ≈6% to ≈9% did not significantly alter the behaviour of the alloys. Mn content was fixed at ≈10% so as to ensure attainment of a

completely or nearly complete austenitic matrix even in the as-cast state. Mn, like Ni and carbon, is also expected to raise the solubility of Cu in cast irons.

A great stress has been laid on the stability of austenitic matrix as a pre-requisite to attaining good corrosion resistance. Its importance can be assessed on the basis of findings in a recent study by Prasada Rao and Patwardhan [Rao(R2)], wherein it was shown that stress relieving adversely affected the corrosion behaviour of Fe-Mn-Cr-Cu cast irons. One of the prime reasons putforward to explain the analomolous behaviour is that stress relieving (at 650°C) lead to the decomposition of the austenitic matrix thereby implying that the matrix was not stable enough.

Copper was added in three distinct amounts ≈1.5,3.0 and 5.0%. Besides aiding the formation of austenite and enhancing its stability, its presence (Cu) was expected to further improve corrosion resistance. Thus in all three alloys were designed with the same base composition i.e. 3.7%C, 6%Cr, 10%Mn and 1.5-2.0%Si but with different Cu contents as indicated below:

C1   ≈1.5%Cu

C2   ≈3.0%Cu

C3   ≈5.0%Cu

3.4 PLANNING OF EXPERIMENTS

The experiments were planned as follows:

PHASE I

A study of structure-property relation by subjecting the alloys to different heat treatments, assessing their hardness and conducting structural investigations by (optical) metallography.

PHASE II

Electrochemical characterisation of the alloy by weight loss method and further detailed structural examination by x-ray diffractometry and by quantitative optical metallography and work on optimization of microstructures.

PHASE III

Deformation behaviour of different microstructures by compression testing and structural investigation by EPMA.

CHAPTER IV

EXPERIMENTAL TECHNIQUES AND PROCEDURE

4.1 ALLOY PREPARATION

Raw materials used for preparing alloys were pig iron, low carbon ferro-alloys (ferro-chrome, ferro-manganese and ferro-silicon), graphite powder, electrolytic copper and mild steel scrap. Composition of the pig iron and the ferro-alloys are reported in the Table 4.1.

The charge consisted of the aforesaid raw materials in the requisite proportions so as to ensure that the desired compositions are attained. Due consideration was given to the metal content of the ferro-alloys and to the melt losses while making charge calculations. Alloys were air melted in clay bonded graphite crucibles in a medium frequency induction furnace.

Initially a base alloy, weighing 65 kgs and containing 3%C, ~5-6%Cr and 10%Mn was prepared by first melting requisite proportions of pig iron, mild steel scrap and graphite to a super-heat followed by deslagging and subsequent addition of ferro-chromium, ferro-silicon and ferro-manganese. After ensuring complete dissolution of alloy additions, small samples were taken out of the melt for estimation of carbon by LECO analyser. In the

intervening period the melt temperature was lowered to reduce losses. After ensuring that the carbon content had reached the desired level, the liquid metal temperature was raised to about 1400°C and slag removed. The molten alloy was then cast into three cylindrical blocks of approximately equal weight. Thus in all three castings were poured.

Finally, the Cu content was adjusted to the desired level (i.e.~1.5, 3.0 and 5%) by adding requisite amount of electrolytic copper to each of the three base alloy castings in the molten condition. Carbon content was rechecked even at this stage to ensure that it was maintained at the desired level. After deslagging, temperature of the molten metal was measured with an optical pyrometer. The alloys were then poured at about 1425°C into ~18 mm diameter X 250 mm long cylindrical moulds and 8x22x120 mm rectangular strips in resin bonded self setting sand moulds.

Alloys were analysed for C,S,P,Si,Mn,Cr on X-ray fluorescence spectrometer. Detailed chemical analysis is reported in Table 4.2.

4.2 SPECIMEN PREPARATION

Alloys were very hard and could not be cut either with a

power saw or with high speed steel tools. Disc samples(height 14 to 18 mm) were sliced off from the cylindrical ingots with the help of a cut-off wheel. Heating of the specimens during slitting was kept to a minimum through water cooling. Specimens thus obtained were ground to have parallel faces and paper polished in the usual manner.

For corrosion studies by weight loss method, specimens of the size ~8x6x4 mm were employed. They were cut from rectangular strips by a procedure outlined above. As before they were ground to have parallel faces and paper polished to the 4/0 stage to obtain mirror finish.

4.3 HEAT-TREATMENT

Heat-treatments primarily comprised soaking at 800, 850, 900, 950, 1000, 1050°C for 2,4,6,8 & 10 hours followed by air cooling. They were carried out in muffle furnaces whose temperatures were measured with a Pt-Pt/Rh thermocouple and controlled to an accuracy of ±3°C.

4.4 HARDNESS MEASUREMENT

4.4.1 MACROHARDNESS

Hardness testing was extensively employed because it provides a quick yet reliable indication of the effect of heat-treatment

on properties.

Heat treated specimens were initially ground to a uniform depth of about 1mm to remove any decarburized layer. Thereafter they were paper polished upto the 3/0 stage in the usual manner. Hardness measurements were carried out on both the faces of a specimen on a Vicker's hardness testing machine employing a 30 kg load. A minimum of 20 impressions were taken on each specimen. The permissible scatter in the hardness values was ±17 VHN [Angus (A3)]. In the event of the variation exceeding this limit, hardness has been represented as a band denoting both the maximum and the minimum values.

As the alloy system under investigation is hetrogeneous in character, the representative hardness readings as well as the average values have been reported.

4.4.2 MICROHARDNESS

Microhardness measurements were carried out on polished and etched selected specimens using a TUKON MICROHARDNESS TESTER (MODEL 300) at 50 grams load and an objective magnification of X200.

Microhardness measurements were made at different locations within a region as also in a number of carbide and matrix regions.

4.5. COMPRESSION TESTING

Deformation behaviour of the different microstructures was assessed by carrying out compression tests. They were carried out on cylindrical specimens (size approx. 10 mm dia x 10 mm height) on a 60 ton capacity West German made MFL microprocessor based universal testing machine, at a cross-head speed of 1.0 mm/min.

4.6. METALLOGRAPHY

4.6.1. OPTICAL MICROSCOPY

This has been extensively employed to study how heat-treatment influenced microstructure. Specimens were paper polished in the usual manner (section 4.2). The final (wheel) polishing was carried out using 1 and 0.1 micron alumina as the abrasives. After proper cleaning, specimen surfaces were etched in freshly prepared alkaline picrate and 2% nital solutions. Metallographic examination was carried out on a REICHERT -JUNG MeF-3 microscope.

4.6.2. QUANTITATIVE METALLOGRAPHY

It was carried out on a LEITZ image analyser (Auto-scan) at a magnification of 3000X. Specimen size was the same as that used during optical metallography. Ten different fields of view were examined on each specimen. Quantitative estimations including plotting of hystograms were carried out with the help of computational techniques.

4.6.3. SCANNING ELECTRON MICROSCOPY

Scanning electron microscopy was also extensively employed on specimens, that had been subjected to corrosion studies in different environments, to asses the nature of damage.

To ensure good elecrical contact, specimens were glued to the specimen holder using a silver base paint. They were then allowed to dry before being examined on a Phillips 501 scanning electron microscope at an opening voltage of 15 KV.

4.7. ELECTRON PROBE MICRO-ANALYSER

This study was carried out for assessing the partitioning behaviour of different alloying elements, particularly Mn,Cr,Cu,C and Si, as influenced by heat-treatment. This was

carried out on CAMEBAX EPMA/SEM at 15 KV and ˜ 60μA beam current using the crystals LiF (for Fe,Cr,Ni and Cu), TAP (for Mn and Si) and ODPb (for Carbon) using the fixed-probe technique.

Specimens for electron probe micro-analysis were cut from rectangular strips, heat treated, and after removing approximately 1mm thick layer from all the faces were cold mounted (mounnt size: 25 mm dia X 7 mm height). The samples, after being prepared for metallographic examination in the usual manner, were etched just enough to reveal the microstructure. This way it was ensured that the composition of different phases/ microconsti- tuents was practically unaltered.

4.8   X-RAY DIFFRACTOMETRY

As-cast and the heat-treated specimens of the alloys were subjected to structural investigations on a PHILLIPS diffractometer PW 1140/90, employing an iron target and a manganese filter, at a voltage of 35 KV and a current of 12mA.

Specimens, which were polished and lightly etched, were scanned from 40 to 150°. Time constant and scanning speed were kept at 2 seconds and 1° per minute respectively. Diffractograms were analysed/indexed by adopting the following procedure.

97

INDEXING OF X-RAY DIFFRACTOGRAMS

Indexing of the diffractograms and a detailed analysis of the probable microconstituents present were done with the help of a computer software package 'XRAY' [Kumar (K5)] as follows:

1. Based on the chemical composition of the alloy and the heat - treatment employed, a list of 196 probable micro - constituents was prepared. This included all constituents that were likely to form as a consequence of possible interactions amongst the alloying elements present eg. carbides, sulphides, phosphides, oxides, silicides etc. including the possible presence of metals (Cu) in an elemental form.

2. Standard 'd'-values, relative intensities, their miller indicies of planes, and lattice parameter(s) for the abovesaid constituents were noted down from the ASTM powder diffraction data cards [JCPOS (J8),(J9),(J10)]. This served as the input data for carryingout the analysis.

3. The experimental error limit for 2θ-matching was taken as $\pm$ 0.2° (the minimum value of 2θ-which can be measured accurately at a chart speed of 1° per cm). The experimental error limit for d-matching was calculated on the basis of this assumption.

4. The computer software performs the following functions:

   a. Experimental error determination for d- matching.

b. Calculation of d-values from 2θ-values and vice-versa.

c. Matching of the calculated d-values or the 2θ-values with the standard values.

d. Prediction of the confidence limit of peak angle/d-value matching as well as the confidence limit of the possible presence of a phase.

e. Reporting of the result of matching in the form of a 2-D matrix and/or in the descending order of confidence limits of the possible phase(s)/microconstituents that may be present.

f. Reporting the miller indicies of planes (arising out of the abovesaid exercise) of the possible phases present.

g. Calculation of the possible peak-angles corresponding to the K_β-radiation.

4.9 DTA STUDIES

DTA was extensively employed to investigate the phase transformation characteristics and for assessing the high temperature response of the different microstructures.

This was carried out on NETZSCH Simultaneous Thermal Analyser STA 409 using KEOLINE as a reference material. A powder sample weighing 45 mg. was taken in an alumina

crucible and heated at a rate of 10°C per minute in air. The experimental data were analyzed and integrated plots of DTA (mV), TG(mg.) and DDTA were obtained as plots through the plotter by NETZSCH DATA ACQUISITION SYSTEM.

4.10. CORROSION STUDIES

Corrosion studies were carried out by the weight loss method.

4.10.1. WEIGHT LOSS METHOD

These tests were carried out in accordance with the relevant ASTM standards [ASTM (A6)]. Specimens were prepared by adopting a procedure outlined in the section 4.2 and cleaned as per the standard procedure laid down [ASTM (A7)]. A specimen was tied to glass rod by a nylon thread/cord. It was then suspended in a 100 ml capacity beaker containing 5% NaCl solution upto a preset level. Each specimen was weighed and its surface area determined prior to being subjected to the test. Tests was conducted for 7 days. After completion of a test, the specimen was cleaned by scrubbing followed by washing in double distilled water, degreasing in acetone and finally air drying [ASTM (A7)]. It was then weighed again and the loss in weight calculated. Corrosion

rates were calculated by using the formula [ASTM (A7)]:

$$\text{Corrosion rate} = \frac{K.W.}{A.T.D.}$$

K= Constant (3.45×10^2) for ipy

K= Constant $(2.40 \times 10^6 XD)$ for mdd

T= exposure time in hours to the nearst 0.01 hour

A= area in cm^2 to the nearst $0.01cm^2$

W= Weight loss in gms. nearst 1 mg

D= Density in g/cm^3

Corrosion rates have been reported in inches per year (ipy) and in mdd(milligrams per square decimeter per day). The latter unit is more reliable since density does not figure in the final calculations.

4.11 DATA ANALYSIS

Analysis of the data obtained was carried out with the help of computational techniques using PC-AT/486.

CHAPTER V

EFFECT OF HEAT TREATMENT ON HARDNESS AND MICROSTRUCTURE

The present investigation was primarily aimed at assessing the heat treatment response of the three alloys namely C1, C2, C3 with the help of hardness measurements, optical metallography, and quantitative metallography.

The results thus obtained have been summarized in the following sections.

5.1 RESULTS

5.1.1 EFFECT OF HEAT TREATMENT ON HARDNESS

Transformation behaviour of the alloys was investigated in the first instance (i) to ascertain the different microstructures that can be generated, (ii) to determine how the heat treating schedule influenced the as-cast hardness, (iii) to assess the effect of composition and heat treatment on hardness and (iv) to characterise the microstructures initially on the basis of hardness. This was achieved by heat treating round specimens (18-20 mm diameter x 14-18 mm height) of the three alloys by air cooling from 800, 850, 900, 950, 1000, and 1050°C after holding for periods ranging from 2 to 10 hours.

Effect of time and temperature on the hardness is summarized in the Tables 5.1~5.34(Table 5.34 summarizes data contained in the Tables 5.1-5.33) and in the Figures 5.1-5.3(the base curves). The data contained in the figures represents the experimentally determined values whereas the actual plots conform to the best fit data. A perusal of the tables and the figures revealed that :

1. The overall transformation behaviour of the alloys could be classified as follows :

    (a) Hardness remaining independent of soaking period on air cooling from 800°C (valid for C1); however for C2 and C3, hardness decreasing marginally with soaking period.

    (b) Hardness decreasing marginally with the soaking period on air cooling from 850°C(valid for all the alloys), the decrease being more pronounced in C2.

    (c) Hardness decreasing marginally with the soaking period on heat treating from 900°C (valid for all alloys); the decrease being more pronounced in C2.

    (d) A slight decrease in hardness with soaking period on heat treating from 950°C(valid for all the alloys); the decrease being a maximum in C3.

    (e) Hardness decreasing with soaking period on heat treating from 1000 and 1050°C (valid for all the

alloys).

(f) The hardness, in general, decreasing with the soaking temperature in the order

$H_{1050} < H_{1000} < H_{950} < H_{900} < H_{850} < H_{800}$

2. There is a general decrease in hardness on heat treating from temperatures between 800 and 1050°C vis-a-vis the as-cast state [valid for all alloys] (Figures 5.1 - 5.3).

3. The aforesaid data(Figures 5.1-5.3) although providing useful information fell short of revealing a comprehensive understanding of the transformation behaviour. The additional information required was obtained by replotting the data contained in the Tables 5.1-5.33 in the following manner :

(i) Effect of time on the hardness as influenced by the heat treating temperature(Figures 5.4-5.9).

(ii) Effect of temperature on the hardness as influenced by the holding period for each alloy(Figures 5.10-5.12).

(iii) Effect of temperature on the hardness at each of the five soaking periods for all the alloys (Figures 5.13-5.17).

(iv) Effect of alloy composition on the hardness as influenced by the heat treating parameters [for each alloy] (Figures 5.18-5.21 which are in the form of bar

diagrams).

The following deductions would reveal the usefulness of the Figures 5.4-5.21 when considered along with the Figures.5.1-5.3, in providing further useful information on the (a) individual and (b) comparative behaviour of the alloy(s).

4. The comparative hardness vs time plots, as influenced by temperature, further confirmed the similarity between C2 and C3 upon heat treating from 800°C; alloy C1 responded differently as is evidenced by hardness remaining unchanged (Figure 5.4).

5. On air cooling from 850 and 900°C, the alloys C1 and C3 responded similarly as revealed by an equivalent rate of decrease in their hardness with time. However, the response of C2 differed showing a constancy in hardness (Figures 5.5-5.6).

6. On air cooling from 950°C, hardness was found to be dependent on time for all the alloys, thereby revealing a basic similarity (a general decrease in hardness with increased soaking time) in their transformation characteristics (Figure 5.7). However the response of C3 (showing steep fall in hardness with time) differed from C1 and C2 (exhibiting an almost similar decrease).

7. On air cooling from 1000 and 1050°C, whereas the alloy C1 showed a marginal decrease in hardness with time, the alloys C2 and C3 revealed a marked decrease which became pronounced at and beyond 6 hours soaking period (Figures 5.8 - 5.9).

8. On heat treating from 1000 and 1050°C, the transformation behaviour was found to be similar for the alloys C2 and C3. Alloy C1 showed the best resistance to softening amongst the three alloys. Alloys C2 and C3 exhibited almost similar hardness levels at 8 hours soaking period both at 1000 and 1050°C (Figures 5.8 - 5.9).

9. (a) The hardness vs temperature plots as influenced by time(Figures 5.10-5.12) represented how effectively each alloy sustained its hardness on heat treating.

(b) These curves had an inverted parabolic shape.

(c) The slope of the curve altered around a threshold temperature called the 'cross over point'(COP). The overall slope varied with the Cu content, its effect being marked at 3%Cu(in alloy C2).

10. The (qualitative) profile of the hardness vs temperature plots(Figures 5.10-5.12) for the three alloys is nearly the same. It was further evident that with an increase

in the heat treatment temperature, the hardness vs temperature plots are acquiring a sharp profile, the effect being marked in all the alloys beyond 900°C.

11. A clear cut COP could not be obtained in most instances for the experimental alloys. However it was observed to be in the range 800-850°C.

12. A comparison of the hardness vs temperature plots as influenced by time(Figures 5.13-5.17), further revealed that:

    (i) At 2 and 4 hours soaking period, the three alloys C1, C2 & C3 responded similarly as is evident from the similarity in the slope of the hardness vs temperature plots. However, C1 sustained a higher level of hardness.

    (ii) At 950°C, 6 hours soaking period, alloys C1 & C2 attained almost identical hardness. On raising the temperature to 1000°C and 1050°C, the overall change in hardness level in C1 and C2 was found to be marginal whereas the response of C3 was different i.e. the decrease in hardness was larger. The rate of decrease in hardness in all the three alloys is not directly related with the Cu content.

(iii) The nature of hardness vs temperature plots at 8

hours soaking period is different from the rest of

the plots as the differences in the hardness levels

in C2 and C3 evened out. The hardness values were

almost similar except at 950°C. The alloy C1 as

although showing a decrease in hardness with

temperature, retained a higher level of hardness

than either to C2 or C3.

13. The bar diagrams summarized in Figures 5.18-5.21 clearly

bring out the individual and comparative behaviour of

the three alloys at a glance besides reinforcing the

different deductions arrived at earlier.

5.1.2 MICROSTRUCTURE

Effect of heat treatment on the hardness was substantiated

by carrying out microstructural examination. Initially the

experiments were confined to assessing qualitative changes in the

microstructure and these are summarized as photomicrographs in

the Figures 5.22-5.42. Subsequently, quantitative estimations

involving massive and dispersed carbides were also carried out.

This data have been dealt with separately.

(a) The microstructure of the alloy C1

1. The as-cast microstructure essentially comprised martensite +

austenite + carbide(Figure 5.22). Volume fraction of massive

carbides was large. (Figure - 5.22a). The carbide phase which was by and large discontinuous had different morphologies namely, (i) eutectic type, (ii) massive/platy type, and (iii) mesh type/flowering (resembling phosphide eutectics). The eutectic carbides were apparently inter-linked with platy carbides (Figures 5.22a-b). Overall the carbides were oriented in different directions. In addition to the above, certain dark etching features with 'leaf like' morphology were also observed (Figure 5.22b).

2. On heat treating from 800°C for 2 hours, the matrix showed needle like precipitation(Figures 5.23a-b) whose morphology became evident at a higher magnification(Figure 5.23b). Its volume fraction was not uniform. The needles had an obtuse plate like appearance although occasionally straight needles/plates were also observed(Figure 5.23b).

On raising the soaking period through 6 to 10 hours, the precipitation of needle type second phase was more pronounced (Figures 5.23f-g). Massive carbides rendered discontinuous and assumed a favourable morphology (Figure 5.23 g). Dispersed spherical carbides were also observed at 6 hours and more so at 10 hours(Figures 5.23c, d, e & g).

3. On heat treating at 850°C for 2 hours, there was a general coarsening of the needles as well as the dispersed carbides

(DCs). DCs appeared to have increased in amount. The matrix now mainly comprised austenite as is evident from the observations carried out at higher magnification (Figures 5.24a-b).

On raising the soaking period to 6 hours, features similar to the above were observed. Apparently, the extent of coarsening was more(Figure 5.24e-f). The matrix mainly comprised austenite and same martensite (Figures 5.24 d,f). It occasionally showed variable etching characteristics (Figure 5.24f). Dispersed particles coalesce (Figure 5.24e-f). Similarly the needles/plates were also seen to link up (Figure 5.24f). The needle "ends" acquired a rounded morphology (Figure 5.24f).

On raising the soaking period to 10 hours, was a general coarsening of the 'obtuse needles'/plates as well as the dispersed spherical carbides(Figure 5.24h). Disintegration/delinking of massive carbides(MCs) which had acquired rounded edges was also observed without any graphite forming(Figures 5.24a-i). An interesting feature was that the dispersed particles acquired a tendency to align themselves along specific directions(Figure 5.24h).

4. On heat treating at 900°c for 2 hours, volume fraction of the needles greatly diminished (Figures 5.25a-b). Simultaneously,

the formation of 'aligned' DCs was observed (Figures 5.25a-b). The disintegration of MCs continued as observed earlier. At 6 hours soaking period, the above said features were somewhat coarsened (Figures 5.25c-d). The volume fraction of the needle type phase had greatly diminished (Figures 5.25 c-d).

On raising the soaking period to 10 hours, there was general coarsening of the DCs (Figures 5.25f-g). The volume fraction of the needles/plates was very small (Figure 5.25 f-g). An interesting feature is that the MCs and the coarsened DCs tended to align themselves. Simultaneously, 'rounding off' at their edges confirmed (Figures 5.25f-g). The austenite matrix showed differently etching regions (Figure 5.25 e-f).

5. On heat treating from 950°C, microstructural features at 2 hours soaking period are not much different from those observed on heat treating at 900°C for 10 hours (Figures 5.26 a-f). An equally important aspect was that the MCs were seen to be linking themselves/approaching one another to link up. A similar tendency was also observed amongst DCs (Figures 5.26b&f).

On raising the soaking period through 6 to 10 hours, the basic features were similar to those mentioned above. However, the morphology of MCs was either near spherical or with

'rounded edges' (Figures 5.26c-d). Occasionally hexagonal shaped carbides were seen(Figure 5.26d). The austenitic matrix etched somewhat differently around some massive / dispersed carbide regions (Figure-5.26b,d&f).

6. On heat treating from 1000°C for 2 hours, there were some marked but interesting structural changes. First of all no needles were present(Figure 5.27a-b). Secondly, linking of DCs, which had by now acquired a favourable morphology, continued resulting in their merging together or interdiffusing(Figure 5.27b). Similarly, the aligned MCs also appeared to link-up with one another (Figure 5.27a). The disintegration and rounding off amongst MCs continued and was more prevalent at 6 hours soaking period (Figures 5.27c-d). The existence of differently etching regions around MCs continued as before (Figure 5.27 d).

On raising the soaking period through 6 to 10 hours, the microstructure now comprised massive carbide regions with favourable morphologies in a matrix of austenite(Figures 5.27e-g). The various tendencies especially the ones involving 'alignment' and 'rounding off' in MCs were in evidence. Dark grey etching regions appeared to develop both around massive as well as around dispersed carbides. The austenite matrix was very 'evenly'/uniformly 'textured'(Figures 5.27e-g).

7. On raising the temperature to 1050°C and at 2 hours soaking period, the 'rounding off' and coalescing tendencies among the MCs were greatly enhanced(Figures 5.28a-c) giving rise to the formation of large 'agglomerates' at higher soaking periods (Figures 5.28d-j). Very often these agglomerates had either a massive or sometimes a 'plate like' morphology. Occasionally regions having either massive or 'plate like' morphologies but with 'rounded edges' were also observed. It appeared as though some of the original DCs have become MCs with rounded or hexagonal morphologies as observed on heat treating for 6 and 10 hours(Figures 5.28e-f & i-j). The 'rounding off' tendency was clearly dominant but equally dominant was also the tendency of 'aligned linking' amongst MCs. In certain areas, 'dark etching' regions appeared to form essentially around MCs or at the interface between two or more massive carbide regions which were joining one another(Figure 5.28g&j). In some instances, stray DCs were also seen to form(Figures 5.27j). All in all, a large number of interrelated changes appeared to be occurring. From the point of morphology of massive carbides, the 1050°C, 6 hours heat treatment appeared beneficial.

(b) Alloys C2 and C3

The structural changes in C2 & C3 are on similar lines as

those in C1 barring some areas of difference centering around:

(i)   type of carbides present in the as-cast state and the nature of the matrix

(ii) the type of the needle morphology, the main precipitating second phase at 'lower temperatures'

(iii) stage(s) at which disintegration/rounding off within massive carbide sets in,

(iv) possible interaction between coarsening/growing needles and dispersed carbides(DCs),

(v)   general state of MCs at high temperature, and

(vii) the extent of the formation of dark/grey etching regions at the highest heat treating temperature, namely, at 1000°C & 1050°C.

Alloy C2

(a) As-cast :   -same basic features as in Alloy C1 (Figures 5.29a-d)

                     -carbides are compact, discontinuous, and less platy compared to C1(Figure-5.29b)

(b) 800°C, 2hours   -needles & DCs are present in the matrix; presence of austenite more readily detected austenite. (Figures 5.30a-b)

     6hours   -needles mostly obtuse in character (as in C1) (Figure 5.30d-e)

115

-feathering is present(Figure 5.30e)

            10hours -basic structure as in 6 hours (Figure 5.30f)

                     -structure more uniform

                     -some   coarsening of needles seen (Figure

                      5.30f)

                     -feathering not apparent

                     -MCs developing rounded edges (Figure 5.30f)

(c) 850°C, 2hours   -general coarsening of DCs(Figure 5.31a)

                     -feathering seen(Figure 5.31a)

                     -DCs are more

                     -discontinuity in MCs(Figure 5.31a)

            6hours   -general   coarsening   of   DSPs/DCs; volume

                      fraction of needles low (Figures 5.31 b-d).

                     -Massive   carbide   morphology discontinuous,

                      favourable.(Figure 5.31b-e)

            10hours -general coarsening of needles/DCs (Figures

                      5.31e-g)

                     -'needle' volume fraction less

                     -alignment of DCs

                     -needles approaching/joining DCs   (Figures

                      5.31g)

(d) 900°C, 2hours   -'uneven' matrix etching(Figures 5.32a-d)

                     -needles & DCs coarsened(Figure 5.32b-e)

-needles & DCs less than in C1

-needles and DCs aligning themselves

-linking up of needles/DCs

-dark etching spots around MCs(Figure 5.32a,b

& d)

6hours -discontinuous MCs with rounded edges (Figures

5.32 e-g)

-dark etching spots around MCs (Figures 5.32

e-g)

-less DCs & needles; linking up/agglomoration

of coarsened DCs

10hours -as above(Figures 5.32h-j)

-DCs appear more in some regions(some of them

may be disintegrated MCs)(Figure 5.32i)

-needles approaching DCs(Figure 5.32i-j)

-rounding of MCs at edges(general)

(e) 950°C, 2hours -rounding of MCs(Figures 5.33a-c)

-dissolved MCs and interlinking of MCs & DCs

observed(Figure 5.33a)

-joining/approaching of MCs(Figure 5.33b)

-both needles & DCs present

6hours -pronounced general disintegration and

'rounding off' of MCs(Figures 5.33d-f)

-DCs are present(Figures 5.33 d-f)

-'haloed' regions(Figure 5.33f)

-linking tendency among needles & DCs (Figure 5.33 f)

10hours -same as above(Figures 5.33g-i)

-DCs coarsened(Figure 5.33g)

-morphology of MCs favourable; they are discontinuous (Figure 5.33 i)

-coarsened DCs appearing as MCs linking up with MCs (Figures 5.33 h)

(f) 1000°C,2hours -matrix plain(Figures 5.34a-c)

-needles almost nonexistent

-DCs are a part of disintegrated MCs (Figure 5.34c)

-linking as before among MCs(Figure 5.34b) and amongst DCs & MCs (Figure 5.34 c) -aligned MCs & DCs

-hexagonal or rounded 'carbides' are present (Figure 5.34b)

6hours -as above(Figures 5.34d-f)

10hours -rounded MCs(Figures 5.34h-i)

-dark grey/light grey regions adjoining MCs (Figures 5.34h - i)

-'haloed' regions around MCs(Figure 5.34g)

-Hexagonal, rounded & some elongated MCs (Figures 5.34 g-i)

-interdiffusion amongst DCs & MCs and between DCs & MCs seen (Figures 5.34 g-i)

(g) 1050°C,2 hours   -rounded, hexagonal, and rectangular carbides observed(Figures 5.35 b,d)

-favourable carbide morphology (Figures 5.35 a,b&d)

6 hours   -grey/dark regions around MCs(Figures 5.35e-h)

-linking up or joining together of MCs

10hours   -joining of large MCs(Figures 5.35 i-l)

-perforated MCs(Figures 5.35k-l)

-general 'morphology' of MCs useful

Alloy C3

(a) As-Cast   -carbides compact, less platy, more discontinuous and lesser in amount (Figures 5.36 a-c)

(b) 800°C, 2hours   -minute platelets/DCs(Figures 5.37a-b)

-straight platelets / needles - curving type (Figures 5.37a-b)

-obtuse needles/plates also present (Figure 5.37b)

-Overall DSPs mostly comprise DCs

        6hours   -as above(Figures 5.37c-e)

                    -Morphology of MCs favourable & discontinuous

                    -DCs marked/prominent(Figure 5.37d)

        10hours   -MCs discontinuous(Figures 5.37f-h)

                    -DCs are present and somewhat coarsened

                    (Figure 5.37h)

(c) 850°C, 2hours   -discontinuous MCs with hexagonal shape

                    (Figure 5.38b)

                    -discontinuous MCs with massive morphology

                    also observed(Figure 5.38b)

                    -'rounding off' at edges already initiated

                    (Figure 5.38a)

                    -DCs somewhat more coarsened (Figure 5.38 b)

        6hours   -as above(Figures 5.38c-d)

                    -DCs apparent(Figure 5.38d)

                    -agglomerating & linking tendency amongst DCs

                    (Figure 5.38d)

        10hours   -matrix 'even textured' than at 2 & 6 hours

                    (Figure 5.38e-f)

                    -coarsening of DCs(Figure 5.38f)

                    -alignment amongst DCs

(d) 900°C, 2hours   -'rounding off' at edges of MCs (Figures

5.39b-c)

-general coarsening

-MCs linking and discontinuous; both platy &
rounded/favourable morphologies present
(Figure 5.39c)

-feathering absent

-formation of dark/grey regions seen(showing
concentration difference)(Figures 5.39b-c)

6hours -same as above(Figures 5.39d-f)

-DCs coarsening(Figures 5.39e-f)

-needles 'rounding off' at edges (Figure
5.39e)

10hours -rounding off as before(Figures 5.39h-i)

-disintegration of MCs(Figures 5.39g-i)

-aligned DCs and agglomerating tendency
amongst DCs and MCs (Figure 5.39i)

-coarsening of DCs

(e) 950°C, 2hours -as above(Figures 5.40a-b)

-MCs linking and alignment observed (Figures
5.40a-b)

6hours -hexagonal carbides(Figures 5.40c-e)

-rest as before

-existence of dark/grey patches continues

121

(Figures 5.40d-e)

-formation of 'haloed regions' around MCs

(Figure 5.40d)

10hours -same as above(Figures 5.40f-g)

-directional growth amongst MCs and DCs

(Figures 5.40f-g)

-general coarsening(both needles and DCs)

mostly latter, (Figure 5.40f)

(f) 1000°C, 2hours -clean matrix(Figures 5.41a-c)

-rounding of MCs

-no needles

-interlinking amongst MCs(Figures 5.41b-c)

-some 'haloeing' around MCs(Figure 5.41c)

6hours -same as above(Figures 5.41d-e)

-interlinking marked(Figure 5.41e)

-rounded MCs(both at the edges and overall)

10hours -MCs coarsening(Figures 5.41f-h)

-aligned MCs/DCs(Figure 5.41f)

(g) 1050°C, 2hours -general rounding of MCs & agglomeration /

interlinking (Figures 5.42a-d)

-formation of grey/dark regions around MCs

lesser than in C1 and C2 (Figures 5.42b-c)

-light grey regions also seen(Figure 5.42a)

-morphology of MCs mostly rounded and also
platy

6hours   -basic features as before(Figures 5.42e-h)

-interlinking of MCs

10hours   -general features as before(Figures 5.42i-l)

-perforated carbides are also seen (Figures
5.42i-j)

-some reprecipitation of DCs observed

On comparing the three alloys(i.e. on increasing the Cu content), the following observations emerged:

(i)   DCs formed at an early stage and were more in number,

(ii)   no trend was observed with regard to the amount of needles,

(iii)   matrix microstructure was cleaner and comprised lesser grey/dark regions(at 1000 and 1050°C); carbide morphology and distribution was better,

(iv)   better morphology of carbides even on heat treating at high temperature.

5.1.3 QUANTITATIVE METALLOGRAPHY

5.1.3.1 MASSIVE CARBIDES

Effect of heat treatment on the volume fraction of massive carbides was investigated with the help of a LEITZ image analyzer. The data thus obtained have been summarized in Tables

5.35-5.38(Table 5.38 summarizes data contained in the Tables 5.35-5.37).

A perusal of these tables revealed that :

1. Volume fraction of the massive carbides in the as-cast condition ranged from 30-45%, it being the highest in C1 and the least in C3. Volume fraction of MCs in C2 was not much different from that in C3.

2. In a majority of instances, an increase in the temperature/time, in general, led to a decrease in the amount of massive carbides.

3. Up to 900°C, the decrease in volume fraction was gradual/minimal.

4. Raising the temperature from 900°C to 1000°C led to a marked decrease in the amount of MCs except in C3 which contained the least amount of MCs even in the as-cast condition. On heat treating from 1050°C, a general marked decrease in the volume fraction of massive carbides with time was observed (valid for alloy C1 and C2). Alloy C3 exhibited marginal decrease in volume fraction of massive carbides both at 1000 and 1050°C.

5. An interesting observation to emerge from the quantitative data is that in most instances with an increase in the copper content, there is a general

decrease in the volume fraction of massive carbides with temperature/time.

6. Increasing the copper content also made the micro-structure(s) more uniform with regard to the variation in and the average volume fraction of massive carbides.

7. To understand the nature of variation at (5) and (6) above, the volume fraction of MCs was plotted as a function of temperature as influenced by soaking period (Figures 5.43-5.45).

(i) such a perusal revealed that the variations conform to a second order polynomial, i.e.

% MCs = K1 + K2.T + K3.T^2 (at t in hours).

(ii) On increasing the Cu content, the overall volume fraction of MCs in the as-cast state decreased,

and (iii) the decrease in the volume fraction of MCs with temperature was a function of time, it being slow at lower soaking periods and gaining in momentum with time.

5.1.3.2 DISPERSED SECOND PHASE(DSPs)

Dispersed second phase(both needles and dispersed carbides) were characterized on the basis of the following parameters :

(i) Total number of DSPs

(ii) their 'size based' distribution

(iii) Volume fraction of the DSPs

(iv) their average particle size and

(vi) Percent number and percent area occupied by the DSPs

in different size ranges

In the present study also[Jain (J2)] particles have been classified on the basis of different size ranges with a mean of 0.58μ; a total of four classes existed.

The data thus generated are summarized in the Tables 5.39-5.43, Figures 5.46-5.47, and in Appendix A-1 to A-3. Figures 5.46-5.47 depict representative hystograms showing a variation in the amount of DSPs at five different locations as influenced by heat treating. The aforesaid data were analyzed in two ways, (a) by assessing whether any general trend existed and (b) by laying down a detailed account of how the heat treating variables affected the parameters employed to characterize the dispersed second phase.

Considering to start with the former, the following general trends were observed for all the alloys:

(i)   Dispersed carbides predominantly belonged to class I(0-0.58μ) and II i.e. size 0.58-1.16 microns(Tables 5.39-5.40 and Appendix A-1 to A-3).

(ii)   The number of particles was a maximum for heat treatments carried out at 800°C and 850°C. (Table 5.41).

(iii) The effect of heat treating parameters on the aaverage number and per cent number of particles, their volume fraction, mean diameter did not conform to a definite trend (Tables 5.39-5.42). Hence this aspect is not being commented upon.

(iv)   In a general way, it can be stated that for a given time, the number of particles in classes I & II decreased or remained unaltered with an increase in temperature. A similar trend was observed on increasing the heat treating time at a given heat treating temperature(Tables 5.39-5.40).

(v)   The changes described in (iv) above were supplemented by a spilt over of DSPs/DCs in class III (Tables 5.39 - 5.40). The extent of these changes was a minimum in C1 and increased with Cu content (Tables 5.39-5.40).

(vi)   Representative histograms summarized in Figures 5.46-5.47 proved extremely helpful in appreciating as to how the distribution of the particles varied with temperature and time at different fields of view/specimen cross section.

5.2 DISCUSSION

The main aim of the present investigation was to establish the transformation behaviour of the alloys. This was achieved by heat treating the alloys from different temperatures after holding for different lengths of time followed by assessing the microstructural changes by hardness measurements. Subsequently, the microstructures were quantitatively characterized by studying the variation in (i) the volume fraction of massive carbide and (ii) the size and distribution of dispersed second phase as influenced by heat treating parameters. The data thus generated proved helpful in modelling (i) the transformation behaviour, (ii) the coarsening behaviour of dispersed carbides, and (iii) the heterogeneity based on the distribution of massive carbides and dispersed carbides as influenced by heat treating parameters.

5.2.1 STRUCTURAL CHANGES DURING HEATING

Before embarking upon this analysis, it would be useful to mention once again that the alloys investigated in the present study were designed to ensure that the matrix comprised austenite with higher stability. This has been achieved by maintaining the Mn content at 10%. The Cr content of the alloys was maintained at 7% on the basis of data generated by Singh [Singh (S10)] who studied the abrasion resistance of 6% and 9% Cr cast irons alloyed with 1% Cu and varying amounts of Mn. The 7% limit

ensured that there was no danger of graphitization occurring even if Cu was employed in larger amounts(as has been presently done). Thus the present set of alloys contained Cr higher than the ones investigated by Jain & Kumar [Jain (J2), Kumar (K6)]. Similarly, the copper levels presently used(up to 5%) are higher than the ones employed earlier [Jain (J2), Kumar (K6)]. Further, whereas the earlier alloys contained up to 7.5% Mn, the alloys presently investigated contain 10% Mn.

It has been established that (a) nearly 45% of the Mn added partitions to austenite and the balance to the carbide phase, (b) bulk of the chromium partitions to the carbide phase, and (c) bulk of the Cu partitions to austenite [Singh (S10)]. This enables an understanding of the ensuing structural changes that will occur which comprise (i) a reduction in the volume fraction of the massive carbides due to the presence of Si and Cu(attributed to their graphitizing tendency), (ii) an increase in the stability of austenite arising out of the dissolution of the additional alloying elements made available as a consequence of (i), and (iii) a possible 'rounding off' of the massive carbides and their being rendered discontinuous due to (i), (iv) occurrence of a carbide transformation which would be governed by the nature of the phase diagrams, and (v) the possible

precipitation of carbides from austenite on prolonged soaking as represented by the reaction

$$\text{austenite} \rightarrow \text{austenite} + DC \qquad \dots(5.1)$$

The likely structural changes therefore, can be summarized with the help of the following equations :

$$\text{austenite} \rightarrow \text{austenite(lesser alloy content)} + DC \quad \dots(5.2)$$

$$MC \rightarrow MC\text{(discontinuous with reduced VF)}$$

$$+ \text{ interstitial and substitutional solutes} \qquad \dots(5.3)$$

$$MC \rightarrow \text{other types of carbides} \qquad \dots(5.4)$$
$$\text{Interstitial} + \text{substitutional solutes} + \text{austenite} \rightarrow$$

$$\text{austenite(with increased stability)} \qquad \dots(5.5)$$
$$\text{austenite(with higher stability)} \underline{\text{increase in SP/ST}} \rightarrow$$

$$\text{austenite(relatively lower stability)} + DC \qquad \dots(5.6)$$

$$DC \quad \text{increase in} \quad \frac{\text{ST at given SP}}{\text{SP at given ST}} \rightarrow \begin{array}{l} DC\text{(coarse)} \qquad \dots(5.7) \\ \text{or possible dissolution} \\ \text{at higher temperature(s)} \end{array}$$
5.2.2 CHANGES DURING COOLING TO ROOM TEMPERATURE

They will be governed by the cooling rate and the alloy content and would primarily be confined to austenite. Some changes may also occur in the massive carbides and the DCs that have formed. The possible changes in austenite would depend upon the temperature and time as they govern the relative stability of austenite in accordance with the Equations (5.2), (5.5), and

(5.6). If air cooling is done, austenite may reject excess solute in the form of dispersed carbides and would subsequently transform to either B/M and or remain untransformed. Since the minimum Mn content in the alloys is appreciably higher(10%) to ensure that no martensite can form on air cooling from 800 and 850°C, it is evident that the transformation product in the present alloys on air cooling would essentially be austenite independent of the temperature from which they are cooled. This tendency is further aided by the amount of Cr that would partition to τ in spite of its being a carbide former. Similarly, Cu would essentially partition to τ only. Any martensite if at all present, may at best be observed on air cooling from 800 and/or confined to the as-cast state.

Carbide precipitation during cooling mainly occurs because of a decrease in the solid solubility of carbon with temperature in the austenite. If austenite is supersaturated after heat treatment, it would reject out excess solute as carbides and these would be inherited by the transformation product of austenite on cooling which in the present situation is most likely to be austenite only and therefore the chances of excess carbon precipitating as carbides are greatly reduced since part of Cr partitioning to it also has large solubility in austenite. If however the austenite is not supersaturated and is in a state

wherein the solute is fully or 'near completely' dissolved (requiring a higher heat treating temperature), it will be retained as such on cooling.

Taking an overall view, the possible structural changes on cooling can be summarized with the help of the following equations :

Slow cooling(as during casting)

austenite --> austenite(τ) + some martensite(M) ?   ...(5.8)

(relative proportion of the τ & M depending upon the Cu content)

Carbide --> unchanged or otherwise, depending upon

carbide transformation   ...(5.9)

Final likely structure : τ + M(?) + MCs

Heat treated condition

(a) lower temperatures 800 and 850°C

austenite --> austenite* + DC   ...(5.10)

austenite* --> τ mostly + M(?) or exclusively τ ...(5.11)

(extent of M, if any, depends upon soaking period i.e. less at lower soaking period and likely to be negligible at higher soaking period)

Massive carbide --> M'C' + M"C" etc.   ...(5.12)

DC --> DC(coarse)   ...(5.7)

Final likely structure : τ + M(?) + MC + DC

(b) Temperatures 900 & 950°C

<u>austenite*</u> --> austenite   ...(5.13)

<u>DC</u> --> DC(coarse)   ...(5.7)

<u>MC</u> --> M'C'+ M"C" + --- (volume fraction reduced)   ...(5.12)

Likely final structure : austenite + DC + MC

(c) 1000 and 1050°C

<u>austenite*</u> --> austenite(matrix completely austenitic)   ...(5.14)

<u>DC</u> --> DC(coarse) and possible dissolution at higher

       soaking period(s) and temperature(s)   ...(5.7)

<u>MC</u> --> M'C' + M"C" + --- (volume fraction low, possible rounding

                    off may be observed)   ...(5.12)

Final likely structure : austenite + MC + some DC(?)

                or austenite + MC

5.2.3 STRENGTHENING RESPONSE OF DIFFERENT TRANSFORMATIONS

Before analyzing the structure-property relations it would be appropriate to consider the strengthening associated with different transformations.

The austenite to martensite transformation leads to hardening and to simultaneous embrittlement. It is of little significance in so far as the present study is concerned. The attainment of austenitic matrices would lead to an improvement in the ease of deformation. In such instances, the stacking fault

energy(SFE) of the matrix would determine the strength-ductility interrelation as it(SFE) controls the extent of work hardening. It is relevant to record here that Mn-austenites have a low SFE and hence exhibit a high rate of work hardening [Patwardhan (P3)].

Massive carbides have a higher hardness and the strengthening response would be directly related to their volume fraction. Its morphology and compatibility with the matrix are also equally important. The latter is governed by the crystal structure. The effect of dispersed carbides would be governed by the volume fraction, compatibility with the matrix, size, shape and distribution [Jain (J5)].

5.2.4 INTERRELATION BETWEEN MICROSTRUCTURE AND HARDNESS

The general microstructural changes that may occur in the experimental alloys, highlighted in the earlier sections, facilitate interpretation of the structural changes that would occur in C1, C2, and C3. As hardness is governed by the microstructure, the two have been discussed together.

5.2.4.1 AS-CAST STATE

The microstructure of the alloys in the as cast condition namely, $m + \tau + MCs$. (Figures 5.22c, 5.29c & 5.36b), could be explained on the basis of the analysis outlined in the sections 5.2.1-5.2.3(Equation-5.8). At 10% Mn the matrix is expected to be

predominantly austenitic. However the high hardness of the alloys in the 'as-cast' state clearly indicates that a fair proportion of martensite is present as is duly supported by microstructural examinations (Figures 5.22 a-b, 5.29a-b & 5.36a-b). This is due to a higher carbon content of the experimental alloys which tends to combine with a relatively larger concentration of alloying elements thereby reducing the overall alloy content of the matrix to an extent that on air cooling a fair proportion of martensite is formed in addition to retained austenite. Quite evidently the lower the overall carbon content the larger would be the tendency to form markensite. Thus the analysis putforth in the section 5.2.1 to 5.2.3 is in no way isolated and explain why the volume fraction of MCs is large in the as-cast state. Apparently the three alloys do differ in some respects especially with regard to the morphology of the massive carbides. While describing the microstructure, three types of massive carbides have been identified, namely, (a) eutectic type, (b) massive/platy type, and (c) mesh type. The amount of type (a) & (b) carbides will be governed by the carbon equivalent of the composition and its(compositions's) disposition with respect to the modified eutectic composition. The (c) type carbide is governed by the phosphorous content which is approximately the same in all the three alloys. Considering the

carbon equivalent of the compositions being investigated on the basis of the data reported by Merchant [Merchant (M8)], the modified eutectic composition is ~ 3.8%. Thus effectively the compositions being investigated are hypoeutectic in nature. The microstructure of alloy C1 does in fact conform to its being hypoeutectic in character by exhibiting a fair proportion of platy carbides (Figures 5.22a-c). With an increase in the copper content of the expected changes would comprise a reduction in the volume fraction of MCs and their being rendered less platy and more eutectic type and discontinuous. This is what has been observed (Figures 5.22,5.29 & 5.36). Thus the microstructures in the as-cast condition are appropriately explained. In the present set of alloys, the strengthening is essentially governed by the amount of martensite and MCs. The latter is directly related to the amount of copper present(the levels of Mn and Si being nearly the same in the three alloys). Accordingly the hardness in the as-cast condition would be the highest in C1 and the least in C3 as has been observed although the overall difference may not be large (Figures 5.1 - 5.3).

5.2.4.2 HEAT TREATED CONDITION

The structural changes in the heat treated condition have been outlined with the help of equations in the sections 5.2.2.1-

5.2.2.3. The prominent changes would be the precipitation of carbides from the austenite during soaking and a reduction in the amount of MCs and their eventual 'rounding off'. In the present context equally important would be the resultant of the breakdown of the martensitic structure in the as-cast state on heating while heat treating.

For the sake of simplicity, transformations in C1 will be initially discussed and subsequently the similarities/ differences between C1 and the transformations observed in C2 and C3.

5.2.4.3 ALLOY C1:

(a) 800°C: The matrix is a combination of martensite + austenite. The interesting aspect is the formation of 'a needle like' and dispersed second phase(Figure 5.23). At 2 hours soaking period the needles formed (Figures 5.23a-b) appear to have etching characteristics similar to the dispersed carbides, more clearly seen at higher soaking periods(Figures 5.23f-g). This leads to an inference that they could either be carbides which is most likely and/or some intermetallics. It is not possible to identify them through optical metallography except on the basis of microhardness measurements. As this proved difficult, the identification aspect has been separately dealt with and would be discussed in the next chapter. The obtuse morphology of some of

the needles, more prominent at higher heat treating temperatures/periods(Figures 5.23f-g), may lead to a mistaken inference that the precipitated phase is martensite. However in the present instance since the matrix is partly martensite, such a possibility is rather remote. Moreover, the 'obtuse plate' feature is observed even on heat treating from higher soaking temperatures. This establishes beyond doubt that the obtuse plates do not represent martensite because the alloys are so designed so as to exclude its formation and to ensure the retention of austenite over a wide range of heat treating temperatures especially on heat treating from higher temperatures. The observation that the tendency to precipitation/coarsen is enhanced at higher soaking period is logical since a larger activation is available for the intended changes at higher soaking periods. The matrix is martensitic independent of the soaking period. Since the precipitation of dispersed second phase lowers the solute concentration of the matrix to a level such that austenite cannot be fully retained.

850°C: On heat treating at 850°C for 2 hours, the major expected changes are a general coarsening and the formation of a larger volume fraction of DCs and DSPs(needle/plate)(Figure 5.24) because the temperature is higher. The coarsening tendencies would be marked at higher soaking periods. This is what has been

observed(Figures 5.24f-h).

The formation of differentially etching regions within the austenitic matrix(Figures 5.24a,c&i) is an indication of 'heterogeneity' which is being sustained/accentuated due to the possible disintegration of MCs(Equation-5.12). As the heat treating temperature is low, the concentration gradients thus formed persist. It is expected to be evened out as the temperature increases. The disintegration of MCs is occurring because of the combined graphitizing action of Cu and Si(as already discussed) whose intensity will increase with temperature. This leads to a reduction in the volume fraction of MCS(which is minimal at·this temperature) and in their being rendered discontinuous to begin with(Figures 5.24b & h).

The most interesting feature i.e. the formation of aligned DCs(Figure 5.24h) suggests the 'precipitating tendency' to be directional which appears reasonable as the precipitating phase will pick out directions of closest packing. This could also be interpreted differently by stating that the 'aligned' carbides are in fact the 'globularized segments' of the precipitating needle morphology being so rendered due the combined graphitizing tendency of Cu and Si. Otherwise no specific reasons exist as to why the carbides should be 'aligned'.

The matrix is now almost entirely austenitic more so at higher soaking periods since solute enrichment of the matrix due to a dissolution of MCs is enough to retain nearly austenitic matrix on air cooling.

900°C: The structural changes at 900°C as influenced by an increase in the soaking period are essentially on similar lines as those observed on heat treating at 850°C(Figure 5.25). Evidently the temperature being higher, the extent of coarsening of DCs and needles and disintegration of MCs will be more marked(Figures 5.25b-d & f). The etching characteristics of the matrix are more or less uniform(Figures 5.25f&g) because the nonuniformity of the matrix vis-a-vis the solute concentration is evened out at a higher temperature(as the present one). However, the special features namely the 'needle ends'(now plate ends) acquiring rounded shapes and 'aligned' precipitation of carbides(both dispersed and massive) are strikingly distinctive in character representing 'preferred directional growth' and needing a more careful analysis(Figures 5.25). Rounding off amongst MCs is occurring to enable them to acquire lower energy configuration(s) at higher heat treating temperatures(section 5.2.1). The austenitic matrix showed differently etching regions revealing a nonuniformity in composition resulting due to the

structural changes mentioned above.

950°C: The microstructures observed at this temperature as influenced by soaking period(Figure 5.26a) are consistent with the reasoning put forward to explain similar changes earlier. Presence of needles is at best limited up to 6 hours which is logical since around this temperature or higher a near spherical morphology is more preferred, more so at higher soaking periods. Rounding off of MCs will be more, the extent of coarsening will be larger and the remaining portions of MCs will acquire lower energy configuration (spherical/hexagonal) particularly so at higher soaking periods since this temperature is the same as that employed for malleablizing [Heine (H5)]. All of these features can be attributed to enhanced diffusion rates at 950°C. Only hereafter would pronounced changes occur in the massive carbide morphology and a marked reduction in their volume fraction(Figures 5.26).

Massive carbide regions are seen approaching one another in an effort to reduce their volume fraction and also perhaps to acquire low energy configurations(Figures 5.26a,d-f). This is a unique feature observed, which although similar to 'diffusion bonding', has neither been hither to reported nor observed so distinctly in alloyed white irons or in other materials where

large sized carbides are present in the microstructure. Although Ostwald-ripening does come close enough to this situation but its occurrence has been mostly observed/confined to dispersed second phase. What is bringing about a similar situation amongst MCs is perhaps the tendency of the alloy to pronounced directional precipitation/growth and a desire to minimize the volume fraction of the second phase with a view to reduce energy.

At some locations 'haloed' regions(representing a different etching character within the matrix) are observed especially around MCs/coarsening DCS(Figures 5.26b,d&e). They may represent regions with a different alloy concentration(indicative of a different strain field compared to the matrix) during the process of carbide growth/coalescence.

1000°C: On heat treating at 1000°C for 2 hours, the changes described at 950°C especially at 10 hours heat treating period are further accelerated.

The observation that the austenitic matrix is relatively clean especially at higher soaking periods is an indication that compositional heterogeneities are minimized and simultaneously the number of transformations occurring within the matrix are at a minimum. This is to be expected in view of the temperature

being high which would contribute to the structure attaining as high a stability as possible. None the less the formation of some small sized dispersed second phase perhaps through a process of reprecipitation is still in evidence(Figures 5.27b-c).

The absence of needles, as on prolonged soaking at 950°C, is a welcome feature and signifies the process of growth to be equiaxial rather than directional as would be expected at high temperatures. For similar reasons, the MCs would acquire morphologies such as 'near spherical' or 'hexagonal'(Figures 5.27d & g) and their volume fraction would reduce. The latter is aided by the observed 'linking up' amongst massive carbides.

The formation of localized dark grey etching regions around massive and dispersed carbides(Figures 5.27c & d) needs commenting upon. Such regions are apparently forming as a prelude to either the DCs or the MCs linking up/agglomerating. There are also instances where isolated MCs are developing dark etching regions around themselves which may be due to the initiation of the formation of a new phase(Figures 5.27c-d). All the aforesaid tendencies will be marked at higher heat treating temperatures/ soaking periods.

1050°C: The prominent features observed on heat treating at 1050°C are essentially an extension of changes occurring on heat

treating at 1000°C(Figures 5.28), namely, (a) general 'rounding off' of MCs, (b) their linking/agglomerating along specific directions, (c) formation of dark grey/dark etching regions around MCs and in the regions separating adjoining MCs, and (c) formation of linkages and eventual 'spherodization'* and/or formation of hexagonal MCs. The only difference is that all of the aforesaid tendencies are marked due to the temperature being higher. The driving force for marked 'agglomeration' amongst MCs is the tendency of the microstructure to reduce its energy. Further, the 'dark grey' and 'dark etching' regions are definitely austenitic depicting solute concentration different from the austenitic matrix- so essential to facilitating the agglomerating/linking up processes(Figures 5.28).

It is of significance that a greater unevenness within the austenitic matrix and the formation of small sized DCs have been observed. In fact the former and the latter add up to suggest that the unevenness is because of initiation of certain precipitation based transformation(s) afresh. The reason for the formation of 'linkups'(Figures 5.28g&i&j) appears to be that they are acting as initiators for the formation of a new(carbide) phase.

---

* Refers to small sized MCs as distinct from the usual MCs or DCs

When these alloys are compared with those investigated by Jain and Kumar [Jain (J2), Kumar (K6)], it then becomes evident that the microstructures in the 6-8% Mn and 5% Cr and 1.5-3.0% Cu white irons examined by them were less complex than the ones being presently observed with regard to (i) the initiation of transformation(s) afresh at a number of points within the matrix even on heat treating at 1050°C and (ii) the formation of varied dispersed second phases. In fact the earlier alloys although free from these changes, none the less suffered from problems resulting from the formation of an 'eutectic type' of platy carbide at lower soaking periods on heat treating at 1050°C. The presently investigated alloys are free from this problem.

5.2.4.4 ALLOYS C2 AND C3

Structural changes observed in C2(Figures 5.29-5.35) and C3(Figures 5.36-5.42) are on similar lines as those described in the alloy C1(Figures 5.22-5.28). Therefore no specific comment is being made so as to avoid repetition.

Taking an overall view, the difference on proceeding from C1 to C3 can be attributed to copper increasing from 1.5% to 5%.

The differences between C1 and the alloys C2 & C3, namely-
(a) the overall incidence of needle morphology being lesser/negligible.

(b) dispersed carbides forming at relatively lower temperatures/
soaking period(s),

(c) disappearance of plates at relatively lower temperature(s)
and soaking period(s),

(d) disintegration amongst MCs being faster and initiated at
lower heat treating temperature(s)/soaking periods,

(e) unevenness of the matrix being lesser except on heat treating
at 1050°C,

(f) overall distribution of MCs being better, and

(g) the overall distribution of MCs at higher temperature being
better, confirm the above reasoning to be correct as the
aforesaid changes are duly related with an increase in the
carbide destabilizing tendency and austenite stabilizing
tendencies thereby enabling structural changes to be
initiated/occur at lower temperature(s) and/or lower
period(s).

A similar reasoning explains why dark grey/dark etching
regions at higher heat treating temperatures are the least in the
alloy C3.

This in essence would conclude the discussion on the nature
of the structural changes. The aforesaid similarities and differ-
ences are clearly reflected in the hardness data and the next

section would therefore be devoted an interrelation between hardness and microstructure. Being a useful indicator of the likely properties, the hardness-microstructure interrelations assume major significance as a precursor to an understanding of the microstructure-property correlations.

5.2.4.5 HARDNESS-MICROSTRUCTURE INTERRELATION

The aforesaid analysis provides a basis for explaining the hardness changes as influenced by the temperature and time.

(a) Alloy C1

Considering the alloy C1(Figure 5.1), on heat treating at 800°C for 2 hours, the hardness is lower than the as-cast hardness because the amount of martensite has decreased with respect to that in the as-cast state. On increasing the soaking period up to 10 hours there is negligible change in the overall martensite content as the tendency to precipitate balances the tendency towards solute enrichment due to the dissolution of massive carbides. A very general gradual increase in hardness with time is due to an increase in the amount of precipitated second phase(needles and/or DCs) (Table 5.35).

On raising the temperature to 850°C, there is little change in the hardness levels over that observed at 800°C as there is

little change in the microstructure. The small decrease in hardness on increasing the period further is an indication that coarsening of the DCs has perhaps set in and at the same time the reduction in the amount of MCs is marginally higher than at 800°C. Similar to the situation at 800°C, the overall hardness is in general dependent of the soaking time. However marginal difference in the hardness levels is an indication that the factors promoting increase and decrease in hardness approximately balance one another.

On heat treating at 900°C, the coarsening of precipitated second phase and a somewhat larger reduction in the amount of MCs(an indirect increase in the amount of austenite) has resulted in the hardness decreasing with soaking period. Evidently, the overall hardness at 900°C is lower than that at 850°C for reasons already stated. A similar analysis would also explain the reasons for a decrease in hardness with time on heat treating at 950°C and also its overall level being lower than the one attained on heat treating at 900°C. It is noteworthy that the decrease in the amount of MCs would be marked hereafter for, reasons already discussed(section-5.2.4.3).

On comparing the hardness levels at 850°C, 900°C, and 950°C at higher soaking periods, the decrease in hardness is getting

marked with an increase in temperature. This is due to (i) the coarsening of dispersed second phase up to 900°C, (ii) its more or less complete disappearance at 950°C, and (iii) more importantly because of an enhanced tendency at reducing the volume fraction of MCs. All these add up to an increase in the amount of austenite and its stability (Equation-5.5).

On raising the temperature to 1000°C, the matrix is practically free from DCs and the reduction in hardness with time is basically due to a reduction in the volume fraction of MCs. A similar situation also exists at 1050°C except that changes occurring are more marked than at 1000°C. The maximum reduction in hardness is occurring at 10 hours soaking period on transiting from 1000 to 1050°C due to (i) a marked decrease in volume fraction of MCs(as a result of enhanced graphitizing/carbide destabilizing tendency) and (ii) an enhanced interdiffusing/ agglomerating tendencies amongst MCs.

(b) Hardness changes in alloys C2 and C3

The hardness changes in C2 and C3(Figures 5.2-5.3) can be interpreted on similar lines. In as-cast state, both C2 and C3 attain almost equal volume fraction of MCs which is lower than that of C1 (C3 attains the least) and accordingly heat treating would have little effect on the volume fraction of MCs in the

149

heat treated condition to begin with(Tables 5.35-5.37), i.e. hardness change is being controlled by the volume fraction of DSPs.

Apart from the above, the other major difference between C1 and, C2 & C3 is that whereas in C1 the hardness remains unaltered or marginally changes with time on heat treating from all temperatures, it is decreasing with time on heat treating, the decrease being more pronounced at 1000 and 1050°C, for C2 and C3. The rate of decrease is maximum in C2 and a minimum in C3 with C2 falling in between. However, the overall hardness is lowest in C3 and highest in C1. All the aforesaid differences are essentially related to the carbide destabilizing/DSPs forming tendencies.

On comparing C2 and C3, the commonality exists heat treating is that the difference in hardness levdels even out with increasing soaking periods except at 950°C where the alloys exhibited broadening (more difference) with increasing soaking periods. The aforesaid observations, namely, the decreasing trend in hardness setting early in C3 and the overall hardness being lower at higher soaking periods can be attributed to a larger copper content in C3 and hence to a larger carbide destabilizing and austenite stabilizing effects. Accordingly the

least hardness is observed in alloy C3 on soaking for 10 hours at 1050°C.

5.2.4.6 COMPARATIVE CHANGES IN HARDNESS IN C1, C2, AND C3 AS INFLUENCED BY HEAT TREATING PARAMETERS

The discussion up till now centered around explaining the base curves(Figures 5.1-5.3). It would now be appropriate to compare the relative behaviour of the three alloys as influenced by time(Figures 5.4-5.9).

The general behaviour of the alloys C2 and C3 is similar on heat treating at 800°C because, overall, the volume fraction of MCs is playing a major role in controlling it. C1 however responded differently(Figure 5.4) more due to a higher initial volume fraction of massive carbides(Table 5.38). A careful study of Table 5.38 can explain the above said behaviour of the alloys. The almost matching hardness levels at higher soaking periods can be attributed to similar Vf of MCs.

The three alloys on heat treating from 850°C are behaving in a similar manner as stated above i.e. at 800°C (Figure 5.5). It is a pointer that the overall contributions of an increasing second phase and decreasing MCs approximately balanced out, the lower initial volume fraction of MCs not withstanding(Tables 5.8 & 5.14).

151

The similarity in C1 and C3 on heat treating from 900 (denoting only a marginal decrease in hardness with time) is due to the overall contributions of DSPs and MCs. At 950°C, the situation is different as the alloys C1 and C2 are showing less rate of reduction in hardness as compared to C3. Such a behaviour can be attributed to almost complete absence of DSPs and to the sufficiently higher temperature (950°C) affecting significantly the stability of the matrix and the carbide transformation (formation) behaviour.

On heat treating at 1000°C, the precipitating second phase is practically absent and the differentiating factor are the rate at which volume fraction of MCs is decreasing with time and the structural changes. The former (Vf of MCs) being equivalent, leads to the similarity in the overall behaviour of the experimental alloys, the latter might account for behaviour of C1 in particular (Figure 5.8, Tables 5.11 and 5.17).

On heat treating at 1050°C, the changes are on similar lines as those indicated at 1000°C, including the 'hardness arrest' at 8 hours soaking period (Figure 5.9, Tables 5.12 and 5.18) and an enhanced carbide destabilizing tendency. Reasons for the former are not clearly understood whilst that for the latter are explained.

Thus overall, the Figures 5.4-5.9 reiterate the commonality and differences amongst the three alloys discussed individually on the basis of the Figures 5.1-5.3.

5.2.5 HARDNESS AND TIME INTERRELATION

The data contained in the Tables 5.1-5.18 and Figures 5.1-5.9 were analyzed with the help of a computer programme to arrive at the aforesaid interrelation. Constants for the first, second and third order variations were calculated using the least square technique [Himmelblau (H10), Mangasarain (M4)] and are also reported at the bottom of each of the Tables 5.1-5.18. Although the variance decreased as the order of equations increased, plotting of the data revealed that the hardness-time interrelation and its interpretation(already discussed) can be best explained on the basis of a first order equation. The calculated values of hardness on this basis(also indicated in the Tables) are in excellent agreement with the experimental values. Thus, hardness H can be expressed by an equation :

$$H = K1 + K2.t \text{ (at a constant temperature)} \quad \ldots (5.15)$$

The values of the constants K1 and K2 for each of the alloys at different heat treating temperatures are indicated in the Tables 5.1-5.18.

153

5.2.6 HARDNESS-TEMPERATURE INTERRELATIONS

5.2.6.1 NATURE OF VARIATION

In order to arrive at the aforesaid correlation, the hardness vs temperature data for each of the alloys(summarized in the Tables 5.19-5.33) were analyzed and the constants for the first to third order variations calculated (Tables 5.19-5.33). It is not reasonable to assume that hardness varies linearly with temperature especially so when changes in the microstructure are being brought about by at least two major transformations. On a similar ground a third or a fourth order variation is also ruled out. Of the available options a second order variation represents the microstructural changes most appropriately which comprise an initial gradual/minimal decrease in hardness which is followed by a marked decrease in hardness at T ≥ 950°C. Hence the variation in hardness with temperature at each of the soaking periods can be most appropriately represented by a second order polynomial :

$$H = K1 + K2.T + K3.T^2 \qquad \qquad ...(5.16)$$

The values of the constants K1, K2, and K3 have been indicated in the Tables 5.19-5.33. This analysis forms the basis of arriving at the hardness vs temperature plots(Figures 5.10-5.17) which are in the form of an inverted parabola.

5.2.6.2 EFFECT OF TEMPERATURE ON HARDNESS AND MICROSTRUCTURE

The aforesaid data summarised in the Figures 5.10-5.12 can be interpreted on a basis similar to the one employed for interpreting the data contained in the Figures 5.1-5.3. However, it is the shape of the hardness vs temperature plots that needs analyzing. As already stated(section 5.2.6.1), the hardness vs temperature plots should have an inverted parabolic configuration i.e. the hardness decreasing somewhat slowly to begin with and gaining momentum after a threshold temperature is exceeded. Since the base microstructure is nearly identical in all the three alloys(austenitic matrix), the hardness changes would be governed by the overall outcome of the two transformations namely, (i) formation of precipitated second phase and (ii) decrease in MCs. As already noted the former increases the hardness whereas the latter decreases it. Evidently, the overall change in hardness with temperature will be very slow to begin with especially at lower soaking periods and in alloy(s) exhibiting the least austenite stabilizing/carbide destabilizing tendencies(i.e. alloy C1) and would gain momentum as more activation is provided by increasing time(Figure 5.10). The extent of activation provided increases with temperature & time at a given temperature and would be more at higher temperatures. This analysis satisfactorily explains the general features of the hardness vs temperature plots(Figures 5.10a-e).

155

The higher Cu alloys C2 and C3 exhibit a near linear behaviour to begin with since the austenite stabilizing/carbide destabilizing tendency in them is larger though no direct relationship with the copper content is observed. Thus the transformation products conducive to sustaining a higher level of hardness may not be so effective(due to their reduced Vf) and therefore the decrease in hardness with temperature and time sets in early in C2 and C3. This explains the data summarized in Figures 5.11-5.12.

The aforesaid analysis would also explain why the COP (signifying a change in the slope of the hardness vs temperature plots) would occur within a narrow temperature range for all the alloys (Figures 5.10-5.12). The maximum decrease in the hardness(hardness band) in the alloys has occurred at 1050°C firstly because this is the highest heat treating temperature employed and secondly because at this temperature the different structural changes leading to a decrease in hardness occur the fastest and to the maximum extent. At 1050°C, the higher the soaking period, the smaller would be the volume fraction of massive carbide and larger the volume fraction of austenite and therefore, the lower would be the hardness(Figures 5.10-5.12).

5.2.6.3 COMPARATIVE HARDNESS VS TEMPERATURE DATA

The comparative hardness vs temperature plots(Figures 5.13-5.17), essentially derived from the data summarized in the Figures 5.10-5.12, indicate the effect of soaking period in influencing H vs T relation and can essentially be interpreted on a similar basis as the one employed for interpreting the Figures 5.10-5.12. The usefulness of the Figures 5.13-5.17 is that they reveal the comparative data at a glance and this is further summarized in the form of bar diagrams depicted in Figures 5.18-5.21.

5.2.7 EFFECT OF TEMPERATURE AND TIME ON THE MORPHOLOGY AND VOLUME FRACTION OF MASSIVE CARBIDES

Although the effect of massive carbides in controlling the overall hardness has been discussed at length in sections 5.2.4.5 & 5.2.6.2, it would be appropriate to comment upon the effect of heat treating parameters on their morphology and volume fraction. Massive carbides present in the as-cast structure(Figures 5.22, 5.29, and 5.36) are partly discontinuous (though still massive) and have been so rendered due to the graphitizing action of Cu and Si(sections 5.2.1- 5.2.3). This tendency, which increases with Cu content, temperature and time, also reduces the volume fraction of massive carbides on heat treating.

Based on physical metallurgical considerations associated with malleablizing in so far as carbide destabilization/disintegration is concerned [Heine (H6)], it is expected that the tendency towards attaining (a) a discontinuous morphology and (b) a reduced volume fraction would become marked at temperature $\geq$ 950°C. Another reason why volume fraction of massive carbides may not significantly decrease until 950°C is that other transformation(s) involving the formation of precipitated second phase as needles and DCs(highlighted earlier) take precedence over the carbide transformation. This is because they require lesser activation in terms of temperature.

However, unlike in malleable irons, the carbide phase in the experimental alloys has been rendered stable by Cr additions. Additionally a fair proportion of Mn also partitions to it, thereby enhancing its stability [Singh (S10)]. Therefore, as the heat treating temperature and time are increased the massive carbides instead of decomposing into graphite, will acquire a low energy near rounded or hexagonal morphologies. The precise nature would be governed by the crystal structure of the massive carbides as influenced by heat treating temperature and time. This analysis explains why (i) carbides are rendered discontinuous, (ii) their volume fraction reduced with temperature and time, and (iii) the 'rounding off' tendency is

observed on heat treating from higher temperatures/periods (Figures 5.22-5.42).

Considering the decrease in the Vf of massive carbides, the Cr containing carbides, as already stated, are further rendered stable because Mn(55-60% of the added amount) partitions to them [Singh (S10)]. Therefore, normally the decrease in the volume fraction of massive carbides will be faster only at temperatures around 950°C or higher(i.e. 1000°C) because this is the temperature at which carbide is destabilized during malleablizing. This is duly supported by the observations discussed earlier(Figures 5.43- 5.45). This process(involving a reduction in the volume fraction of massive carbides) will be further aided by the presence of a fully austenitic matrix and this occurs in the experimental alloys even in the as-cast state. This may account for a reasonable reduction in the Vf of MCs even at temperatures lower than 950°C.

Although copper is a mild graphitizer, the carbide destabilizing tendency is directly proportional to the copper + silicon content. An important effect of raising Cu content will be that the volume fraction of MCs in the as-cast state will reduce and the reduction in the Vf of MCs will set in at lower temperatures/soaking periods. Thus the data summarized in Table

5.38 and in Figures 5.43-5.45 thus stand appropriately explained. The least volume fraction of massive carbides will be observed at the highest soaking temperature and time(Table 5.38).

An analysis of the manner in which MCs decreased revealed that an increase in the soaking period had only a marginal effect at least to begin with and gathers momentum with time more markedly at higher temperatures. It was therefore felt appropriate to quantify the decrease as a function of temperature at different soaking periods(Figures 5.43-5.45). On doing so it emerged that the plots should logically follow a second order variation, namely, the same as the one observed when the variation in hardness with temperature as influenced by soaking period was considered(Figures 5.10-5.12). Evidently the data in Figures 5.43-5.45 would be interpreted similarly as the one in Figures 5.10-5.12.

5.2.8 EFFECT OF TIME AND TEMPERATURE ON THE DISTRIBUTION OF DISPERSED SECOND PHASE

Sections 5.2.1-5.2.2 highlight the mechanism of formation of dispersed second phase from austenite. The results summarized in the Tables 5.39-5.43, Figures 5.46-5.47, and in Appendix A-1 to A-3 prove helpful in characterizing them comprehensively. Particles constituting the dispersed carbides have a size up to

1.16μ because they exclusively fall into classes I and II at the formation stage. This is valid for all the alloys. On heat treating, their distribution is altered in a manner consistent with the attributes of nucleation and growth type of transformations. Simultaneously, coarsening would also set in. This would lead to a reduction in the number of particles in the first two classes and a simultaneous increase in their number in the class III or higher. Additionally, the mean diameter would also increase. This is what has been observed in a majority of the instances. The main deviation is that a 'general coarsening' is followed by a phenomenon in reverse. This is because, after a certain stage of heat treating the matrix begins to dissolve the DSPs leading to a decrease their mean diameter as well as in their numbers(which is also reflected in the Vf getting reduced(Tables 5.39-5.43). The extent and the stage at which this sets in would be governed by the τ- stabilizing tendency of the matrix and the carbide destabilizing tendency. This in the present instance is being controlled by the Cu content as well as by heat treatment parameters and accordingly the extent of coarsening is lesser in C2 and C3 and the 'carbide' dissolution tendency sets in early(at lower heat treating temperature/time) in C3. In fact, for similar reasons C2 and C3 does not exhibit a marked tendency towards coarsening. Such a thinking could also

161

form a useful basis for analyzing the data related with DSPs in a general sense.

The comparative data given in the Tables 5.39-5.43 reveal that it would not be easy to arrive at a broad based correlation between composition and heat treating parameters with coarsening. Arriving at such an understanding is of interest as the coarsening behaviour & heterogeneity of distribution would govern the overall properties of the alloys. Till date Ostwald's equation [Burke (B-14)] given below is the most authentic formulation for studying the coarsening behaviour of second phase particles, i.e.

$$r_1^3 - r_0^3 = k(t_1 - t_0) \qquad \qquad ...(5.17)$$

where r_1 = particle radius at time t_1, and

r_0 = particle radius at time t_0

A major limitation of this equation is that a large number of data points are required to ascertain its validity/to ensure its application under a given set of experimental conditions. Moreover the equation merely correlates the arithmetical mean of particle radius with time but in no way reflects upon how the particle distribution is influenced by heat treating parameters. Further, finding out the arithmetical average of particle radius does not represent the true picture since the particle size distribution is statistical in nature. In the present investigation the data related with the second phase are available for

all soaking periods at a given temperature. Generally, this should have sufficed for any further analysis of the data but not so with the above equation especially when it is intended to represent distribution. The difficulties arising thus were resolved by evolving a new parameter called the 'coarsening index'(CI) [Jain (J2)].

In order to calculate coarsening index, it is necessary to first evolve a parameter which can represent particle size distribution for a given heat treating schedule. Development of such a parameter was greatly facilitated by the manner in which the quantitative metallographic data was generated, namely, the (a) categorization of particles into different classes, (b) assessment of the number of particles in different classes, (c) calculation of percent number and area occupied by particles in different classes, and (d) measurement of the average particle diameter. The new parameter termed the 'distribution factor'(DF) which incorporated the variables (a) to (d) is defined as [Jain (J2), Patwardhan (P6)]

$$DF = \frac{\sum\limits_{i=1}^{n} X_i \cdot N_i}{\sum\limits_{i=1}^{n} N_i} \qquad \qquad \ldots (5.18)$$

where, n = the number of classes,

N_i = the number of particles in i^{th} class,

X_i = volume fraction in the ith class /VDC,

and, VDC = total volume fraction of dispersed carbides.

Distribution factors, calculated on the basis of the aforesaid formula, are summarized in the Table 5.44.

Having defined this parameter(DF), the coarsening index can now be calculated with respect to a specified reference base - a concept also implicitly in-built into the Ostwald's formula. In the present instance, this reference base was taken to be the heat treating schedule at which the dispersed carbide particles/DSPs just about formed namely the heat treating schedule corresponding to which dispersed carbides/DSPs were present in classes I and II only.

The coarsening index(CI) is thus defined as

$$CI = \frac{DF \text{ for a given heat treatment}}{DF \text{ for the h/t with particles in classes I \& II}} \qquad ...(5.19)$$

Based on the above formulation, the coarsening index for the different alloys was calculated and is summarized in the Table 5.45.

As already discussed above, the aforesaid table proved

extremely useful in assessing the relative coarsening tendency of the different alloys (Table 5.45).

The data on the relative coarsening behaviour of the alloys is relevant to an understanding of their deformation and the corrosion behaviour as would be evident from an analysis put forth in Chapter VII.

Although the aforesaid analysis does explain the data obtained in a majority of instances for all the alloys, a number of data points did not follow a specific trend(Table 5.45). A possible reason could be that the system under investigation is intrinsically 'heterogeneous'. This is evident from the representative hystograms summarized in Figures 5.46-5.47 and from the data given in Appendix A-1 to A-3. This reporting not withstanding, it became prudent to analyze/interpret the entire data more comprehensively/methodically. A possible methodology is to assess the percent number and percent area occupied by particles of different classes as influenced by heat treating parameters [Jain (J2), Kumar (K6)]. This may lead to incomplete/erroneous assessments as is evident from the data summarized in the Tables 5.46-5.48. To overcome this problem, instead, DF was calculated for each heat treatment(Tables 5.49-5.51). Subsequently for each heat treating temperature, the

DF was plotted as a function of time for the experimental alloys(Figures 5.48-5.50). Their perusal revealed that-

(i)   particles predominantly precipitate in class II(size 0.58-1.16μ)

(ii) with an initial increase in temperature(800/850°C), further precipitation in the same ranges occurs; this is followed by coarsening

(iii) with an increase in temperature or time at a given temperature, an initial tendency towards precipitation gave way to the coarsening tendency predominates.

(iv) the changes in class I sized particles are mostly prefunctory in alloys C2 & C3 in general. However in C1 they seemed to assume relevance even at 900°C and their importance persisted even on heat treating at 950°C and 1000°C.

(v)   the relevance of Class III type particles was a function of the alloy (Cu) content and heat treating schedule. Class III particles had little relevance in alloy C1. Its relevance appeared to increase with Cu content and was a maximum in alloy C3 (especially on heat treating at 950°C and 1000°C). A similar situation had partly existed in C2 upon heat treating from 950° at higher soaking periods. Thus taking an overall view, alloy C1 exhibited DSPs

belonging to class I and II, the alloy C2 mostly comprised DSPs in size range 0.58-1.16 µ (Class II) with a spillover into class III whereas DSPs in the C3 comprised a size fraction 0.58-1.16 µ upon heat treating up to 900°C and in the size range 1.16-1.74 µ (Class III) upon heat treating from 950°C and 1000°C.

The aforesaid analysis is quantitatively re-substantiated through the data summarized in the Table 5.52 which reveal the percent contribution of DF in each class as influenced by heat treatment. An important objective of doing so is to arrive at homogeneity/heterogeneity based on the size and distribution of the DSPs. This aspect has been separately dealt with in a later section 5.2.11.

5.2.9 MATHEMATICAL MODELLING OF THE TRANSFORMATION BEHAVIOUR

Figures 5.1-5.3 reveal how time and temperature control the transformation behaviour and therefore, the hardness of the experimental alloys. It was concluded that hardness, H varies linearly with time, t and can be represented by

$$H = K1 + K2t \qquad \qquad \dots (5.15)$$

The values of K1 and K2 were found to be different for different temperatures(T) and therefore can be expressed as a function of temperature in the form of equations

$$K1 = f(T) \qquad \ldots(5.20)$$

$$K2 = f(T) \qquad \ldots(5.21)$$

The plots of K1 vs T and K2 vs T revealed that the K2 vs T is linear and gives a relationship K2 = A3 + A4T. However, the ln K1 vs 1/T plots indicated a linear behaviour and hence, the relation between K1 and T can be expressed as :

$$\ln K1 = \ln A1 + A2.(1/T) \qquad \ldots(5.22)$$

$$\text{or} \qquad K1 = A1.e^{A2/T} \qquad \ldots(5.23)$$

Substituting for K1 and K2 in the equation 5.15, the final relationship is

$$H = A1.e^{A2/T} + (A3+A4T)t \qquad \ldots(5.24)$$

The constants A1, A2, A3, A4 were calculated for different alloys using the multi-variable nonlinear constraint optimization technique [Hiemmenai (H10), magasarain (M4)]. The final equations along with the overall standard deviations are reported below :

C1 : $H = 271.701\ e^{838.513/T} + (0.005809-0.5476x10^{-5}T)t$

$$\text{Overall SD} = 1.593 \qquad \ldots(5.25)$$

C2 : $H = 342.517\ e^{551.093/T} + (0.01686-0.158x10^{-4}T)t$

$$\text{Overall SD} = 4.524 \qquad \ldots(5.26)$$

C3 : $H = 287.256\ e^{692.334/T} + (0.01777-0.163x10^{-4}T)t$

$$\text{Overall SD} = 3.053 \qquad \ldots(5.27)$$

Where T = temperature in °K

t = time in seconds

H = hardness, HV$_{30}$

The theoretical hardness values calculated from the above equations were plotted against the corresponding experimental values and are shown in Figure 5.51. It reveals that barring a few instances, the calculated values are well within ±5%.

It is observed that the constants A1, A2, and A3 are positive for all the alloys. Hence their effect would be similar and additive. The constant A4 is negative and therefore, its effect needs to be analyzed. This calls for assessing the contribution of second factor of the Equation 5.24. Its values, as influenced by the heat treating temperature and time are given below. As will be evident, the contribution of the factor becomes negative at temperatures ≥800°C for C1 & C2 and 850°C for C3.

Contribution of the second factor

Heat-treatment	Contribution of the second factor		
	C1	C2	C3
800 2 AC	0	0	2
800 4 AC	0	-1	4
800 6 AC	-1	-2	5
800 8 AC	-1	-3	6
800 10 AC	-2	-4	9
850 2 AC	-2	-6	-4
850 4 AC	-4	-13	-8
850 6 AC	-7	-19	-12
850 8 AC	-9	-26	-16
850 10 AC	-12	-33	-20

900	2 AC	-4	-12	-9
900	4 AC	-8	-24	-19
900	6 AC	-13	-37	-29
900	8 AC	-17	-49	-39
900	10 AC	-22	-61	-49
950	2 AC	-6	-18	-15
950	4 AC	-12	-36	-31
950	6 AC	-19	-54	-47
950	8 AC	-25	-72	-63
950	10 AC	-31	-90	-79
1000	2 AC	-8	-23	-21
1000	4 AC	-16	-47	-43
1000	6 AC	-25	-71	-65
1000	8 AC	-33	-94	-86
1000	10 AC	-41	-118	-108
1050	2 AC	-10	-29	-27
1050	4 AC	-20	-58	-55
1050	6 AC	-31	-88	-82
1050	8 AC	-41	-117	-110
1050	10 AC	-51	-147	-138

It will be seen that the contribution of this factor to the overall hardness varies linearly with time for a given h/t temperature.

The above discussion reveals that the term $(A3 + A4.T)t$ has a significant impact on the overall hardness especially when the alloys are being heat treated either from 'higher' temperatures or for longer soaking periods.

Because of a difference in the nature of the contribution of the second factor, as influenced by temperature, further calcula-

tions were made to find out the temperature at which the contribution of the aforesaid factor became negative. The change over occurred at 802, 800, and 817°C in C1, C2; and C3 respectively, which are in fact, the temperatures representing the cross-over point(section 5.2.6.2). This deduction is valid for all the alloys, duly remembering that the value of the COP would differ from alloy to alloy.

When the values of COP(obtained from the Figures 5.10-5.12), namely, 850-900°C are compared with those observed on the basis of the model, the apparent difference can be explained by stating that whereas the equations represent transformations without reflecting upon their complexities, the actual situation is to the contrary due to heterogeneity of the system and also because a large number of phases with greatly different 'inherent' characteristics are participating in the transformations. The lag between the 'ideal' and 'actual' situations is what is contributing to the difference and evidently can not be computed mathematically.

5.2.9.1 PHYSICAL CONSISTENCY OF THE PROPOSED MODEL

The data summarized in the Tables 5.53-5.55 , when viewed in the context of the structural changes already discussed, leads to certain important inferences. Firstly, the hardness is essen-

tially controlled by the parameter $A1.e^{A2/T}$. This is independent of the matrix microstructure, i.e, independent of whether the matrix is martensitic/austenitic, or simply austenite as in the present case. Recalling the basis on which the alloys are designed, it is easy to visualise why the matrix is austenitic irrespective of the heat treating temperature employed. Its hardness values vary inversely with temperature, with time at best playing a secondary role, as has been observed (Tables 5.53-5.55).

The contribution from the second factor, although less significant to begin with, assumes prominence at higher temperatures and soaking periods. The parameter $(A3 + A4.T)t$ can therefore, be said to represent the carbide transformation. At lower temperatures ($\sim$800°C for C1 and C2 and 850°C for C3), its contribution is positive and increases with time because the precipitated second phase (DSPs/DCs) is in a condition to harden/strengthen in view of its size and distribution. The correctness of this analysis is proved by the data obtained on heat treating from 850°C, wherein the contribution has decreased due to some coarsening of the DSPs. The contribution, on heat treating from 850°C is quite significant thereby signifying that the precipitated second phase is still playing an effective role.

The negative contribution is seen to have a sizable effect only on heat treating from upwards of 950°C, a temperature at which hardness begins to decrease with time markedly. It is thus noteworthy that the negative contribution is assuming reasonable proportions just when the Vf of MC is beginning to decrease. By this temperature, the DSPs have grown considerably and become less in number, it can be assumed safely that the DSPs seized to be effective and hence the second factor is now representing 'massive carbide' related transformations. Therefore its(second factor) magnitude will increase steeply (i) as the temperature is raised beyond 950°C and (ii) at higher soaking periods at a given temperature. The reasons for the negative contribution of this parameter, with an increase in temperature, have already been analyzed in the section 5.2.7. Therefore, the two parameters constituting the model are physically consistent with the attendant microstructural changes; the first term representing the matrix transformations and the second term the carbide transformations.

5.2.9.2 'SIMULATION' OF THE TRANSFORMATION BEHAVIOUR THROUGH MODELLING

As is known, the overall transformation behaviour of the alloys has been arrived at on the basis of a total of 30 experi-

ments per alloy. This is a time consuming exercise. If it were possible to arrive at/or simulate the transformation behaviour of the alloys on the basis of a minimum yet optimal number of experiments with an accuracy equivalent or there abouts to that of the models developed, then it would greatly help in cutting down on arduous experimentation and would also lead to a saving on energy and the overall costs.

Recent studies by Patwardhan, Mukundan, Rao, Sharma, and Kumar [Patwardhan (P9)] have shown that the transformation behaviour of Fe- 5Cr-1.5Cu cast irons containing 7.5% Mn and 6% Mn with austenitic and martensitic matrices studied on the basis of 30 arduous experiments and mathematically modelled [Patwardhan (P10), could be 'simulated' on the basis of either 4 or at the maximum 6 data points. They comprise hardness values at two extremes of heat treating temperature & time, namely, 800°C(2 hours & 10 hours) and 1050°C (2 hours & 10 hours) and at an intermediate temperature namely 850°C/900°C(2 hours and 10 hours). The logic of selecting the intermediate is that the hardness should be independent of time i.e. dH/dt = 0. This also made the choice of the heat treatments, selected for the purpose of simulation, more representative/broad based.

It was felt appropriate to apply the concept thus developed

to assess whether the transformation behaviour of the alloys C1, C2, and C3 could be similarly 'simulated'.

On following the procedure outlined by Patwardhan et.al. [Patwardhan (P9)], the following emerges-

The 'models' representing the transformation behaviour of the experimental alloys(section 5.2.9) are-

C1 : $H = 271.7 \ e^{838.513/T} + (0.005809-0.54 \times 10^{-5} T)t$

$$\text{Overall SD} = 1.5931 \quad \text{...(5.25)}$$

C2 : $H = 342.517 \ e^{551.093/T} + (0.01686-0.158 \times 10^{-4} T)t$

$$\text{Overall SD} = 4.524 \quad \text{...(5.26)}$$

C3 : $H = 287.256 \ e^{692.334/T} + (0.01777-0.163 \times 10^{-4} T)t$

$$\text{Overall SD} = 3.053 \quad \text{...(5.27)}$$

The hardness values predicted on the basis of the above models are summarized in the Tables 5.56-5.58.

On selecting the hardness values at the two extremities of heat treating temperature & time, namely, 800°C(2 hours & 10 hours) and 1050°C (2 hours & 10 hours), the 'simulated' models are-

C1 : $H = 204.5 \ e^{1051.1/T} + (0.0114-0.1111 \times 10^{-4} T)t$

$$\text{Overall SD} = 14.844 \quad \text{...(5.28)}$$

C2 : $H = 222.4 \ e^{1013/T} + (0.00872-0.9167 \times 10^{-4} T)t$

$$\text{Overall SD} = 6.752 \quad ...(5.29)$$

C3 : $H = 204.5\, e^{1051/T} + (0.01144 - 0.1111 \times 10^{-4} T)t$

$$\text{Overall SD} = 4.955 \quad ...(5.30)$$

On the basis of the above models, hardness values at different temperatures and periods were computed and are summarized in the Tables 5.56-5.58. Interestingly the correlation coefficients for C1 and C3 match closely and approach unity, where this is not so for C2. Thus, there appeared to be no direct relationship between correlation coefficients and the Cu content of the alloys.

On selecting the hardness values at two extremities of heat treating periods (2 hours & 10 hours) at 800 & 1050°C and at an additionally selected heat treating temperature(900°C), the simulated models are-

C1 : $H = 235.87\, e^{902.75/T} + (0.0143 - 0.1334 \times 10^{-4} T)t$

$$\text{Overall SD} = 12.683 \quad ...(5.31)$$

C2 : $H = 265.34\, e^{835.39/T} + (0.01229 - 0.1199 \times 10^{-4} T)t$

$$\text{Overall SD} = 4.824 \quad ...(5.32)$$

C3 : $H = 235.87\, e^{902.75/T} + (0.0143 - 0.1334 \times 10^{-4} T)t$

$$\text{Overall SD} = 3.448 \quad ...(5.33)$$

On the basis of the above models, hardness values at different temperatures and times were computed and are summarized

in the Tables 5.56-5.58. The correlation coefficients of this model are slightly better than the ones obtained on the basis of similar models outlined in Equations 5.28-5.30. Higher correlation coefficients (revealing improved relation between the 'actual' & the 'simulated' behaviour) have been obtained because the selection of hardness values at two extremities of periods at the three heat treating temperatures has made the exercise more representative vis-a-vis transformation behaviour.

Thus the transformation behaviour can be simulated with reasonably high accuracy on the basis of either four or six data points. The correlation coefficients first decrease and then increase with copper content and are minimum in alloy C2 whereas maximum in C1. No satisfactory reasoning based on theory could be assigned to this because it is understood that highr Cu content will reduce the level of heterogeneity through exercising better control over the 'carbide related' transformations. For example, at higher copper contents (alloy C3) the starting volume fraction of massive carbides is low (38.2% in as-cast condition) compared to alloys C1 and C2 which contain 44.9% and 38.7% volume percent of MCs in the as-cast state. The same trend was followed on heat treating from lower temperatures (upto 900°C) as evident from Table 5.38. However, on heat treating from higher

177

temperatures (≥950°C), the trend is changed and the alloy C3 exhibit more Vf of MCs than C2, and in some cases even more than C1 (Table 5.38). This increased Vf of MCs, with attendant heterogeneity, might acount for the above said behaviour i.e. there is a first decrease and then increase in the correlation coefficients with increase in copper.

5.2.10 MATHEMATICAL MODELLING OF THE DISTRIBUTION FACTOR

A critical analysis reveals that the DF can be mathematically represented with the help of the following equations :

C1: $0.04049\ e^{2646.47/T} - (7000 - 5.818T) \times 10^{-8}.t$ ...(5.34)

C2: $0.00407\ e^{4905.09/T} - (7000-5.980) \times 10^{-8}.t$ ...(5.35)

CP3: $0.00079\ e^{6945.10/T} - (7162-6.040T) \times 10^{-8}.t$ ...(5.36)

The basis of arriving at these equations is the same as the one on which the mathematical modelling of the transformation behaviour of the alloys was carried out(section 5.2.9).

5.2.11 HOMOGENEITY/HETEROGENEITY OF THE ALLOYS

A careful perusal of the data summarized in the Tables 5.35-5.37 and especially the one pertaining to the volume fraction of massive carbides as influenced by heat treating parameters reveals that for a given heat treatment, the amount of massive

carbides varied over a considerable range. Higher values are obtained close to the core of the specimens and lower values were obtained towards the periphery. This is primarily due to the inhomogeneities which are intrinsic to alloys/system. The usual statistical methods available to analyze such a data did not prove useful since if mean and the $\pm 3\sigma$ limit(indicative of 95% reliability) are applied to find out the permissible range over which the parameter being assessed could vary, then all the experimental values fall within the ambit of 'permissible' data. The aforesaid observation and the resulting implications are being analyzed separately.

It was however opined by Patwardhan [Patwardhan (P2)] that variations in the data indicate a lack of homogeneity and therefore this could become a basis for calculating the homogeneity/heterogeneity of the alloy(s)/alloy system under investigation.

In a broad sense homogeneity of the experimental alloys can be adjudged on the basis of:

(i) a variation in the alloy concentration within the austenitic
   matrix- chemical homogeneity/heterogeneity,

(ii) uneven distribution of MCs, leading to a highly variable
   volume fraction of MCs and thereby to a variable homogeneity

which may be termed as distributional heterogeneity; additionally carbide transformations and carbide destabilizing tendency will also contribute to this situation.

(iii)uneven distribution of precipitated second phase(variation in size, distribution, and volume fraction discounting the morphology to begin with).

Assessing homogeneity/heterogeneity at (i) would require an accurate assessment of the (a) alloy concentration and (b) the concentration gradients, if any. Such an information could be generated through extensive electron-probe micro analysis which although used in the present study may not prove sufficient to arrive at the desired assessments. Thus the main emphasis would be on assessing the homogeneity/heterogeneity at (ii) and (iii). To begin with the one at (ii) would be addressed to.

In order to fully appreciate the nature of variation, curves were plotted for the experimental alloys depicting all 20 observations(Vf of MCs) as influenced by heat treating para-meters. Representative data thus obtained is summarized in the (figures) Appendix A-4 to A-9. Interestingly the data points do not reveal the existence of 'median points'(or similar data points) which otherwise could have enabled 'assessment' of the

'average'/reasonably relevant value. It was therefore decided to consider all the data points and to arrive at the 'mean' in the usual manner. Having done so, the overall homogeneity/heterogeneity of the alloy as influenced by heat treating has been defined as

$$H_M = \frac{\text{The net variation in Vf of MCs around the mean}}{\text{Permissible variation around a mean}} \quad ..(5.37)$$

$$= \frac{\dfrac{Vf_{exp} \times \text{overall standard deviation(exp)}}{\lfloor Vf_{max,exp} - Vf_{min,exp} \rfloor}}{\dfrac{\text{permitted standard deviation around the mean} \times Vf_{exp}}{\lfloor Vf_{max,per} - Vf_{min,per} \rfloor}} \quad ..(5.38)$$

$$= \frac{Vf \times SD_{exp}}{\lfloor Vf_{max,exp} - Vf_{min,exp} \rfloor} \times \frac{[Vf_{max,per} - Vf_{min,per}]}{Vf \times SD_{per}} \quad ..(5.39)$$

$$= \frac{SD_{exp}}{SD_{per}} \times \frac{[Vf_{max,per} - Vf_{min,per}]}{\lfloor Vf_{max,exp} - Vf_{min,exp} \rfloor} \quad ..(5.40)$$

To calculate SD_{per}, we recall that a given parameter being measured can have values $Vf_{ave} \pm 3\sigma$. This concept can be extended further by stating that under the existing constraints(i.e. for a permitted variation of 15%),

$$\frac{3\sigma_{per}}{\sqrt{n}} = 15\% \times Vf_{ave} \quad ...(5.41)$$

where   n = number of readings

σ_{per} = permissible variance

Hence σ_{per} = SD_{per} = 15% x $\dfrac{\sqrt{n} \ x \ Vf_{ave}}{3}$

$$SD_{per} = 0.15 \ x \ \dfrac{\sqrt{n} \ x \ Vf_{ave}}{3} \qquad \qquad ...(5.42)$$

and for a 15% permissible variation in the Vf of MCs

$$Vf_{max,per} = Vf_{ave} + 0.15 \ x \ Vf_{ave} \qquad ...(5.43)$$

$$Vf_{min,per} = Vf_{ave} - 0.15 \ x \ Vf_{ave} \qquad ...(5.44)$$

H_M could be expressed as a fraction or percent. Under ideal condition H_M = 1. $Vf_{max,per}$, $Vf_{min,per}$, and SD_{per} could be computed on the basis of the error limit permissible e.g. ± 15% or higher as the case may be except in a situation where H_M exceeds 1.

This homogeneity can be described as 'intrinsic' or compositional homogeneity. However, if it were possible to predict 'theoretically' the Vf of MCs an alloy should attain for a given heat treatment, then another parameter 'theoretical homogeneity' can be defined which would be given by the expression-

Homogeneity (theoretical/optimal),

$$Vf_{exp} \ x \ SD_{exp} \ x \ [Vf_{max,per} - Vf_{min,per}]$$

$$H_M(Th/opt) = \frac{}{SD_{per} \times Vf_{theo} \times |Vf_{max,exp} - Vf_{min,exp}|} \quad ..(5.45)$$

This would additionally require estimating Vf_{theo}. To do so a possible basis would be to theoretically compute the Vf from the Vf vs t(at a given T) and also from Vf vs T(for a given t) model and to arrive at a mean of the two values. Thereafter the permissible variation($\pm$20% or $\pm$15%) will have to be considered to arrive SD_{per} as before. The ratio of the compositional to the optimum/ theoretical homogeneity could then reflect upon the deviation exhibited by the alloy/alloy system to heat treating.

To begin with H_M was calculated on the basis of the equation 5.40 for a variation of $\pm$15%. The data thus computed is summarized in the Table 5.59. The implications of this data are being analyzed and this aspect does not form a part of this thesis.

The other form of heterogeneity namely, distributional heterogeneity could result from the unevenness of size/distribution of the precipitated dispersed second phase whose nature has already been commented upon. Variation in it could then be utilized for expressing 'distributional heterogeneity and as per the concept developed [Patwardhan (P2)] could be defined on the basis of the following consideration.

Distributional heterogeneity, H_M(dist) (related with precipitated second phase) could then be expressed as

$$= \frac{\text{Deviation in distribution function/factor with respect to the majority size fraction}}{\text{Overall distribution function/factor}} \qquad \dots (5.46)$$

or more precisely

$$H_M(\text{dist}) = \frac{\text{underspill ratio X spillover ratio}}{\text{overall distribution factor}} \qquad \dots (5.47)$$

expressed as a ratio or as percentage.

The data summarized in the Table 5.60 puts forth such an information and this proves additionally useful in understanding the structural changes already quantitatively and qualitatively discussed. It would be interesting to analyze the impact of such a variation on properties- a theme which has been left out of the ambit of the present investigation.

The concept of determining the homogeneity/heterogeneity based on the data generated through quantitative metallography has not been hitherto pursued/evolved and the following additional steps are suggested to explore this idea/concept further:

(i) a systematic and detailed reporting of the quantitative data on the lines outlined in the present investigation and some of the earlier investigations [Jain (J2), Kumar (K6)].

(ii) a more detailed and comprehensive analysis of the data to
assess the nature of 'events' it represents and the
implications there off.

It is however certain that the earlier assessments regarding
the possible effect of heat treating parameters and copper on the
extent of homogeneity/heterogeneity are perhaps over simplistic
as would be evident from a perusal of the Figures A-4 to A-9 and
the data summarized in Tables 5.59-5.60.

5.2.11.1 3D PLOTS REPRESENTING INTERRELATION BETWEEN TEMPERATURE, TIME AND HARDNESS

Till now the effect of heat treatment on the hardness has
been analyzed on the basis of varying one of the parameters while
keeping the other a constant. This has been represented in
Figures 5.1-5.21. Although, these plots provided useful and nece-
ssary explanations of the transformation behaviour, they failed
to provide the overall effect of heat treatment at a glance.

This difficulty was resolved by constructing 3-dimensional
plots(Figures 5.52-5.54) using the Equations 5.25-5.27, at rota-
tion angles 45° and 225° around the Z-axis and at a tilt angle of
30°. For each of the alloy, Figure (a) represents a gradual
change in the slope of the hardness vs time plots as influenced
by temperature which are represented over a surface. The Figure

(b) clearly reveals that the so called COP is not a sharply delineated temperature but that the change over is occurring over a narrow dark region represented by a surface.

A comparison of the Figures (a) for the experimental alloys further brings out that the slope of the hardness vs temperature/ time plot is generating a surface which has been depicted in Figures (b). The 3-D plots reaffirm the relative differences in the transformation behaviour of the three alloys.

5.2.11.2 ISO-HARDNESS PLOTS

Iso-hardness plots were made by plotting out hardness(as influenced by temperature and time) as contours(Figures 5.55-5.57). Evidently, the hardness is a constant along a contour and as such it would be possible to determine the different tempera-ture and time combinations(from the plot) to get a desired hard-ness. The existence of approximately equally spaced contours with a gradual change over of the slope/orientation in alloy C1 is because it sustains hardness over a longer range of heat treating temperature(s) and period(s). A nearly similar situation exists in C2 and C3 at lower temperature regions, however significant change is observed in these alloys at higher temperatures which exhibit greater flexibility in attaining hardness levels lower than what could be attained in C1.

The aforesaid observations while reinforcing the earlier deductions vis-a-vis the transformation behaviour of the alloys do bring about additional useful information. The data thus obtained could be related to enhanced austenite stabilizing/ carbide destabilizing tendencies resulting from an increase in the copper content.

5.2 CONCLUSION

This chapter has dealt at length with the transformation behaviour of the experimental alloys characterized on the basis of hardness measurements and the attendant microstructural changes. A detailed analysis of the latter proved extremely helpful in arriving at a qualitative understanding of the interrelation between microstructure and properties(indicated by hardness). The behaviour of the dispersed second phase as influenced by heat treating schedule has been mathematically represented by evolving a parameter called the 'distribution factor'. This enabled calculation of the coarsening behaviour of the second phase on the basis of a parameter called as the 'coarsening index'. The evolution of these parameters has proved extremely helpful in overcoming the limitations of the Ostwald's ripening formula which is regarded as the sole basis for

characterizing the distribution of the second phase particles. The development of these models has proved useful in establishing models interrelating properties with the microstructure. This has been discussed in Chapter VII. An equally interesting aspect has been to quantify/define 'heterogeneity'/'homogeneity' on the basis of the distribution of massive second and dispersed second phase as influenced by heat treating parameters.

Finally mathematical models have been developed inter-relating hardness with the heat treating temperature and time (microstructures). It has been established that the model is physically consistent i.e. it truly represents the structural changes occurring on heat treating. With the help of empirical modelling, it has been possible to establish that the transformation behaviour of the alloys could be 'simulated', with nearly equivalent accuracy as the modelled ones, on the basis of 4 to 6 experiments as against the original thirty. This is an important contribution which is of major technological significance.

Although much has been said about the characterization of different phases, the presence of martensite could not be unequivocally established in marginal cases. Similarly, the nature and types of carbides needed identifying. Therefore, a detailed study comprising X-ray diffractometry and EPMA was carried out. The data thus obtained have been discussed in the next chapter.

CHAPTER VI

PHASE ANALYSIS AND PHASE IDENTIFICATION

6.1 STRUCTURAL ANALYSIS BY X-RAY DIFFRACTOMETRY

Specimens of the alloys in the as-cast, as well as in the heat treated conditions were extensively examined by X-ray diffractometry to identify/confirm (i) the nature of matrix microstructure, and (ii) the nature of different carbides that formed during heat treatment. The data emerging from an analysis of the x-ray diffractograms has been summarized in the Tables 6.1-6.22. Summary tables(Tables 6.23-6.25) have also been prepared to make the discussion more concise. With the help of diffraction data, it was possible to interpret the micro-structures more or less fully as would be evident from the ensuing analysis inspite of restricting the experimental work to sepecimens that were cast and heat treated for 6 hours at different temperatures primarily due to time constraints. None the less it just about sufficed to surmise the likely events occurring on heat treating for 2 hours and 10 hours.

6.1.1 RESULTS

6.1.1.1 AS-CAST CONDITION

The microconstituents attained in the experimental alloys comprise a matrix of austenite with some martensite and carbides

namely M_3C (isomorphous with Fe_3C) + M_7C_3 (isomorphous with Cr_7C_3) and M_5C_2. Additionally, Fe_8Si_2C, $CrMn_3$ and elemental copper were also indexed. Lower angle peaks corresponding to a/M were observed in all the alloys. However, the higher angle peaks characterizing martensite were found to be absent in all the three alloys.

6.1.1.2 HEAT TREATED CONDITION

On heat treating, the 2θ values of the matrix differed from the standard 2θ-values as obtained from the diffraction data cards(Tables 6.2-6.22). Further the nature of carbides formed and the presence/absence of other constituents observed in the as- cast state also differed. This along with the effect of heat treating temperature and time on the possible transformations occurring within the matrix and the carbides, and any additional features that were observed, have been discussed below.

6.1.1.2.1 EFFECT OF HEAT TREATMENT ON THE MATRIX MICROSTRUCTURE

(i) On heat treating from 800°C the matrix essentially comprised austenite and martensite.

(ii) A similar situation existed on heat treating from 850°C .

(iii) Increasing the temperature further resulted in the attainment of austenitic matrices.

6.1.1.2.2 EFFECT OF HEAT TREATMENT ON THE NATURE OF CARBIDES

On heat treating, a clear cut carbide transformation sequence was observed. However, the main difference was with regard to the carbide stability as influenced by heat treating parameters and the alloy (copper) content.

(i) M_3C

(a) This is a commonly occurring carbide in the as-cast condition. It was clearly indexed in C1 and C2 but not in C3.

(b) On heat treating, it was indexed in C1 up to 950°C, (6 hours heat treatment) and in traces for the 1050°C, 6 hours heat treatment.

(c) Amongst the three alloys, it was indexed at best in traces on heat treating from 1050°C in C1.

(d) The beheviour of alloy C2 was similar to C1 execpt on heat treating at 900°C where it could not be indexed.

(e) In C3, the indexing of the M_3C carbide is random i.e. the regularity of its occurrence as in C1 and C2 is missing. However, the M_3C carbide was indexed up to 1000°C, 6 hours heat treatment (except at 950°C, 6 hours heat treatment).

(ii) M_7C_3

This carbide formed in all the alloys both in the as-cast as well as in the heat treated condition. Heat treating parameters

seemed to have little effect on its formation/indexing. In all the three alloys, it has been indexed with greater certainty as compared to the M_3C carbide. It was indexed best in C2.

(iii) $\underline{M_5C_2}$

Its presence in the experimental alloys was detected in as-cast and heat treated condition (up to the maximum heat treatment temperature i.e. 1050°C, 6 hours heat treatment). Its indexing showed a trend approaching to that observed for the presence of M_7C_3 carbide and certainly better than that for M_3C carbide.

6.1.1.2.3 OTHER FEATURES

(a) Elemental copper :

Copper was indexed in the as-cast condition as well as in the heat treated condition in all the alloys. Overall its presence appeared to be less marked in C1 whereas it was indexed best in C3, whereas in C2 its indexing was almost approaching that observed in C3.

(b) Fe_8Si_2C:

It was invariably indexed both in as-cast as well as at all the heat treatments.

(c) CrMn₃ :

It was present in the as-cast and in the heat treated conditions. It was indexed only upto 900 °C though found on treces at 1000°C, 6 hours heat treatment for C1. Overall the alloy C3 appeared less susceptible to its formation. The needle like constituent observed through optical metallography may represent this constituent since inter-metallics are known to have a needle like appearance.

6.1.2 DISCUSSION

6.1.2.1 MATRIX MICROSTRUCTURE

A summary of the findings relating to the matrix microstructure has been presented in the Section 6.1. The alloys presently investigated were primarily designed to attain an austenitic matrix on air cooling from all temperatures. Optical metallography had revealed that there is in fact a deviation from this premise and that the matrix comprised austenite and martensite on heat treating from 800°C (all soaking periods) and 850°C (up to 6 hours soaking period). Reasons for the deviation observed have been critically analysed and explained in the section 5.2.4. The x-ray observations have proved useful in supporting and confirming these findings. The matrix microstructure is expected to be only austenitic (refer alloy design) on heat treating from 850°C (higher soaking period) or

from higher temperatures (independent of the soaking period). This is duly confirmed from the diffractometric studies (Tables 6.2 - 6.25).

As the heat treating temperature is raised or time at a given temperature is raised, the volume fraction of MCs decreased (Equation-5.3). The solute atoms thus made available will dissolve into austenite increasing its stability/the lattice parameter. This tendency would be marked at or above a threshold temperature at which the tendency to dissolve the MCs/DCs is also marked. An increase in the lattice parameter will mean that the diffracted beam will shift towards lower 2θ values for austenite. Its magnitude is not easy to assess. To overcome this problem, the maximum intensity peak in each diffractogram (heat treating temperatures $\geq 900°C$) has been attributed to austenite.

6.1.2.2 CARBIDE TRANSFORMATION

Based on an analysis of the data contained in Section-6.1.1.2(Tables 6.2-6.22 and summary(Tables 6.23-6.25), it is evident that the general carbide transformation sequence in the experimental alloys is as follows:

Carbide(s)	Temperature regime
M_3C + M_5C_2 + M_7C_3	As-cast state in all the investigated alloys

$M_3C + M_5C_2 + M_7C_3$ up to 850°C (M_3C present in traces in C3)

|

$M_5C_2 + M_7C_3$ up to 1000°C in C1 and C3
up to 1050°C in C2.

|

$M_5C_2 + M_7C_3$ up to 1000°C, in C2 and C3

$+ M_3C$ (reforming)   up to 1050°C in C1.

|

M_5C_2 (some/traces)
$+ M_7C_3$ up to 1050°C

|

Predominant carbides at high temperature are $M_7C_3 + M_5C_2$
(small traces)

A study of the Fe-Mn-C and Fe-Cr-C ternary diagrams revealed that M_7C_3, M_5C_2 and $M_{23}C_6$ are essentially high temperature carbides and the last mentioned one has a relatively lower dissolution temperature/thermal stability as compared to the other two [Owen (O2)]. Further, the predominant carbide at lower temperatures is M_3C. Accordingly, the carbide expected to be present in the as-cast state should be M_3C as this is the stable form at room temperature. The possible presence of higher temperature forms of carbides can be explained by stating that because of the complexity of the alloy system under study, the different high temperature carbides have not fully transformed

195

successively to their lower temperature variants due to the reactions being sluggish. This can also be looked at differently as would be evident from the discussion below.

The attainment of M_5C_2 and M_7C_3 carbides in the as-cast/heat treated condition with the M_3C carbides playing at best a secondary role affirms that what was outlined in 'design of alloys'(attainment of high temperature microstructure/carbides with a minimum of processing) has in fact been achieved. Equally satisfying is the absence of 'boundary carbide' $M_{23}C_6$.

Looking to the general trend of the data summarized in the Tables 6.23-6.25, it is evident that the carbide transformation occurring in the alloys could be visualized as follows:

(i) retention of the 'high temperature carbides' M_5C_2 & M_7C_3, attained in the as-cast condition, even on heat treating

(ii) gradual phasing out of M_3C(room temperature/lower temperature form) upon heat treating which is governed by the "temperature regime" of stability. This is what has been observed. The only additional feature is that M_3C is reforming on heat treating from $1000^\circ C$ and $1050^\circ C$.

6.1.2.2.1 THE M_3C

This carbide (in massive/platy form) was present up to

950°C. It was found to be isomorphous with Fe_3C, although small amounts of Mn and Cr were also present in it as confirmed through EPMA(Tables 6.26-6.28) to be discussed latter. This in fact made the Fe_3C more stable [Goldschmidt (G2)] otherwise it might have dissolved/transformed even at relatively lower temperature(s) and soaking period(s). On the other hand the presence of Cu in the alloys(although not partitioning to Fe_3C) has an opposite effect and therefore, the dissolution of this carbide is enhanced. This could also be gauged from the subtle differences in the temperature range of stability of M_3C in the alloys C1(1.5% Cu) and C2(3%Cu)(Tables 6.23 & 6.24) although C3 totally differed from C1 and C2 in this regard(Table 6.25). Further, it appears that the phasing out of M_3C is in some way linked with the formation of higher volume fraction/larger proportions of M_5C_2 and M_7C_3 carbides. Whether M_3C could directly transform to M_7C_3 or via an intermediate carbide M_5C_2 carbide needs to be looked at carefully.

6.1.2.2.2 THE M_7C_3

This carbide was present in the as-cast condition and upon heat treating from practically all temperatures. It may be Cr based (Cr_7C_3), Fe based (Fe_7C_3), or Mn based (Mn_7C_3), but Cr_7C_3 is the only carbide to form singly. Others namely Fe_7C_3 or Mn_7C_3 are always present in combination as $(Cr,Fe)_7C_3$, $(Fe,Mn)_7C_3$, or

$(Cr_7C_3 + Mn_7C_3)(103)$ [Goldschmidt (G2)]. In the present study the carbide formed was a mixed carbide of Fe, Cr & Mn(Table 6.27) with a preponderance of Fe & Cr atoms(Table 6.27).

The formation of M_7C_3 has been the subject matter of a number of studies and its mechanism of formation from M_3C has been described as (i) in-situ [Wever (W6), Smith (S11), Pickering (P13), Nutting (N1), Woodhead (W8), Mills (M12), Kuo (K10)] (ii) combination of in-situ and separate nucleation [Honeycombe (H11), Bilby (B9)] and (iii) also as separate nucleation [Balluffi (B2)]. In the presently investigated alloys, a part of the MCs comprise M_7C_3. Its appearance was not similar to the one described in earlier studies [Jain (J2), Kumar (K6)] nor could it have formed "in-situ" as suggested earlier. The additionally forming M_7C_3, coinciding with the phasing out of M_3C, is most likely to be 'nucleated' at the M_3C-matrix interface. In the absence of any $M_{23}C_6$ forming, the earlier hypothesis that it is the dissolution of $M_{23}C_6$ carbide which may initiate the formation of M_7C_3 [Rao (R2), (R4)] would not hold good under the existing conditions. Thus one could visualize a transformation sequence

$$M_3C \longrightarrow \text{metal atoms} \longrightarrow \text{nucleation/ formation of } M_7C_3 \qquad \dots(6.1)$$

6.1.2.2.3 THE M_5C_2

As has already been stated, the M_5C_2 carbide is present even

in the as-cast condition; reasons for its presence have already been stated. Its persistence even upon heat treating(even when the dispersed second phase is absent) could be attributed to the successful implementation of alloy design strategy which aims at attaining the high temperature carbides even in the as-cast state. Inertness and sluggishness of M_5C_2 to transform to the 'other carbide' forms have also contributed to its retention in the microstructure. Evidently, M_5C_2 carbide constitutes a part of the MCs. Additionally, a part of the DSPs comprise M_5C_2 in addition to M_3C. This observation is consistent with the carbide transformation sequence as observed in the Fe-Cr-C and Fe-Mn-C ternary systems [Metals Hand Book (M11)]. By careful perusal of Table 5.42, it can be deduced that there is a general decrease in the volume fraction of dispersed carbides with soaking period up to 6 hours and thereafter an increase on raising the soaking period to 10 hours(Table 5.42). The volume fraction of dispersed carbides initially incresed in all the experimental alloys with increasing heat treatment temperature (up to 850°C). It was followed by either little change or an increase at 900 and 950°C (barring few exceptions) and finally an increase at 1000°C. Both these observations in a nut shell reveal that some new carbide is definitely forming and it would not be incorrect to deduce that this is in fact M_5C_2. Further, a carbide such as the one

199

presently under consideration i.e. forming through a
precipitation process by ageing of austenite is more likely to
be of a dispersed type. Hence at least a part of the dispersed
carbides comprise $M_5 C_2$. This can be established unequivocally
only through selective etching techniques and or by EPMA.

6.1.2.2.4 $Fe_8 Si_2 C$

Even after considering various possibilities of indexing
diffractograms, some peaks still remained unidentified. One of
the possible options considered was the presence of the aforesaid
phase. From the Tables 6.2-6.22, it can be observed that this
phase is indexed in all the alloys up to 1050°C either in traces
or in small amounts. Other than this no further comment is being
made as to its mechanism of formation and/or the morphology it
assumes.

6.1.2.2.5 PRESENCE OF ELEMENTAL Cu AND OTHER PHASES

The possible presence of Cu in the as-cast condition and its
being indexed even on heat treating in spite of the matrix being
by and large austenitic (exceptions heat treating at 800°C and
850°C up to 6 hours) is additionally an unexpected result.
However, results (Tables 6.23-6.25) are in agreement with the
composition of investigated alloys the presence of Cu being best
indexed for C3 i.e. alloy with maximum Cu (5% Cu) and with less

certainty in C1 (1.5% Cu). Quite clearly its difficult to putforth a highly satisfactory explanation as to its presence on the basis of physical metallurgical principles especially when the matrix is austenitic. Its presence is easier to comprehend when the matrix is eithr martensitic or ferritic as Cu has low solubility in them. A detailed EPM analysis confirmed the presence of Cu-rich phase (Table 6.32) in C3 (5% Cu).

After considering all possibilities, some reflections still remained unindexed. It was observed that this problem could be partly resolved by considering the formation of $CrMn_3$ and Cu_2S phases. The possibility of the formation of inter-metallics such as $CrMn_3$ is more on heat treating from higher temperatures. The formation of Cu_2S is feasible in all the alloys perhaps more so in the higher Cu containing alloys. It is suggested that a more detailed investigation is required to confirm the presence of phases such as $CrMn_3$ and Cu_2S etc. in future studies especially since even the possible presence of a carbide of the type Cr_3C_2 is indicated.

Before concluding, a comment regarding the possible indexing of $Mn_{15}C_4$ would be in order. Evidently this carbide is not forming in the experimental alloys. Its inclusion in the Tables 6.23-6.25 meant to convey that the mixed carbides to form come

close enough to a composition not much different from $Mn_{15}C_4$.

6.1.2.3 CONCLUDING REMARKS

The above said analysis can be concised to pin point the deductions/tentative conclusions arrived on the basis of x-ray diffractometry:

(i)   matrix of the experimental alloys is affirmed to be austenite and martensite in the as-cast condition and upon heat treating from 800°C and 850°C and fully austenite upon heat treating from temperatures ≥ 900°C.

(ii) bulk of the MCs comprise M_3C, M_5C_2 and M_7C_3 upto 900°C and mostly M_7C_3 and some M_5C_2 thereafter.

(iii) DSPs (needle & globular morphology) mostly comprise M_3C and M_5C_2; the plate/needle morphologies etch similarly as the MCs and therefore there are reasons to believe that they are carbides rather than being inter-metallics of the type $CrMn_3$; this needs a more detailed analyis through EPMA.

(iv) indications of the possible presence of Cu and other phases such as Fe_8Si_2C, $CrMn_3$ etc. make it incumbent to carry out detailed EPM analysis

(v)   the above said line of approach would also help in identifying the 'haloed' regions around MCs(light grey &

dark grey) as well as dark etching regions often present between two bridging massive carbide regions on heat treating from 1000/ 1050°C.

6.2 ELECTRON PROBE MICRO ANALYSIS RESULTS

This was carried out on the experimental alloys to ascertain (i) the distribution of major alloying elements into the matrix and the carbide phase, (ii) the manner in which the distribution was affected by heat treating/alloying(copper content), (iii) the type of carbides constituting the MCs, DCs and DSPs(needle/plate type), (iv) whether Cu was present, and (v) the identity of the 'haloed' regions around MCs and new regions/ phases such as dark etching areas abridging agglomerating MCs. The relevant data is summarized in the Tables 6.26-6.32 and in the Table 6.33 and in Figure 6.1a-1.

The analysis of the data will be specific to the points that have been mentioned above.

6.2.1 ELEMENTAL DISTRIBUTION

6.2.1.1 AS-CAST CONDITION

The distribution of alloying elements into the matrix and carbide phases is illustrated in the Tables 6.26-6.28. Representative micrographs are summarized in the Figure 6.1.

(i) . A larger amount of Mn partitioned to the carbide than to the matrix phase. The ratio of Mn in the carbide to Mn in the matrix was approximately 1.6 and this was uniformly so for all the three alloys except in C2 wherein it was still higher (Tables 6.26, 6.27 and 6.33).

(ii) Majority of the Cr partitioned to the carbide phase as is evident from the high ratio of Cr in the carbide to that in the matrix (Tables 6.26, 6.27 and 6.33).

(iii) Bulk of the Cu and Si were present in the matrix (Tables 6.26 and 6.27).

(iv) Carbon distribution ´into the carbide and matrix phases is on the expected lines (Tables 6.26 and 6.27).

6.2.1.2 EFFECT OF HEAT TREATMENT ON ELEMENT DISTRIBUTION

The above said observations concerning element distribution are also valid in the heat treated condition. However there are certain additional observations meriting consideration(Tables 6.26-6.33), namely:

(i) The amount of Mn partitioning into the matrix was a maximum in C1, minimum in C2 and intermediate in C3 (though it showed minimum variation with time and temperature) irrespective of the fact that all the three experimental alloys had similar Mn content. There is apparently no

relationship between the amount partitioned and heat treatment temperature/time.

(ii) The concentration of 'C' within the matrix decreased on raising heat treatment temperature/time for C2 and C3 in general. However, in C1, the variation in 'C' concentration as influenced by heat treating parameters did not conform to a specific trend. Alloy C2 showed a more consistent partitioning of carbon into matrix, compared to the other two alloys.

(iii) Cr partitioning into the matrix showed a much better consistency in comparison to either Mn or C. The amount partitioned was found to be a maximum in the as-cast condition (valid for C1 and C3).

(iv) As stated earlier, Cu & Si mainly partitioned to the matrix, and heat treating did not have an appreciable effect on their partitioning.

(v) An important observation is that heat treating did not have a tangible effect on the amount of Mn & Cr present in the MCs.

6.2.1.3 NATURE OF MCs

While discussing the microstructural changes, three types of carbide had been mentioned, (a) massive/platy and (b) eutectic/discontinuous type and (c) flower and perforated type.

All of them etched bright during optical metallography. However, on observing under an electron micro-probe analyzer, the eutectic/discontinuous type and massive carbides appeared differently as grey and dark etching areas respectively (Figure 6.1 a, b & e)

On heat treating the distinction in the etching characteristics between two types of carbides persisted (Figures 6.1a-c, h & c). A perusal of Tables 6.27 & 6.28 indicated that the compositions of the two carbides also differed.

6.2.1.4 IDENTITY OF THE DIFFERENT CARBIDES

Based on the element distribution data, it can be inferred with reasonable certainty that -

(i) In all alloys, the MCs present are of M_7C_3 & M_3C type :

(ii) The higher the temperature the more favoured the presence of M_7C_3.

6.2.1.5 IDENTITY OF DSPs

Identifying the 'needle' like phase and dispersed carbides proved extremely difficult because of their size and the difficulty in focussing. The limited information available suggested these to be carbides (Table 6.29 & Figure 6.1i).

6.2.1.6 IDENTITY OF HALOED REGIONS & DARK ETCHING AREAS ADJOINING MCs

Representative election density images of the aforesaid regions are shown in Figures 6.1a,b,c,d,e,h,i,k and l. Considering the former (haloed regions) to begin with, it is clearly seen that these represent a carbide whose composition is similar to that of the MCs except for the Cr content which is less by 10 % (Tables 6.27, 6.28 and 6.31). Similarly the "C" content of these regions was also somewhat lower than normaly associated with carbides.

The dark etching regions adjoining the agglomerating carbides (Figure 5.1e, h) contained approximately the same amounts of Mn, Cr and C as the massive carbides but additionally also contained Cu & Si (Table 6.30). This indicate that these regions reperesent areas having an alloy concentration different from the rest of the matrix.

6.2.1.7 IDENTIFICATION OF Cu

Copper was observed in the as-cast as well as in the heat treated conditions. This has been duly supported by EPMA observations (Table 6.32 & Figure 6.1f and g).

6.2.2 DISCUSSION

The EPMA data which has been critically represented in the above sections needs to be carefully analyzed to arrive at useful inferences regarding the partitioning behaviour and its consequent impact on alloy design. Equally important would be to resolve the unanswered queries arising out of x-ray diffractometry and optical metallographic analyses such as the identity of the MCs and DSPs and the identity of the differently etching matrix regions obtained on heat treating from high temperatures. Although a more extensive EPM analysis would have proved substantially more beneficial, the experience gained thus far could serve as a basis of arriving at useful conclusions.

The primary interest in such studies centers around the basic partitioning data and as Mn is being given primacy, the initial interest would centre around its partitioning. Subsequently partitioning behaviour of Cr has also been commented upon. Overall, the partitioning ratio $Mn_{carbide}/Mn_{matrix}$ in the present study has varied from 1.35 (only in a few instances) to 1.75. This appears to be in fair agreement with an earlier study conducted by Singh [Singh (S10)] in which this partition ratio was found to be 1.5. and by Kumar [Kumar (K6)] where the partition ratio was found to be 1.5-1.8. The difference, however, is that in the former the heat treating temperatures did not

exceed 850°C, whereas in the latter temperatures have been relatively higher as is also the case in the present study. This difference in itself can account for the slightly larger partition ratios presently obtained.

Looking to the heterogeneous nature of the microstructure certain generalizations can be arrived at regarding the partitioning data which have also been appropriately explained.

(i) $Mn_{carbide}/Mn_{matrix}$ ratio in the as-cast state is relatively unaffected by heat treatment except on heat treating from high temperature when the ratio reduced(valid for Cl & C2. This could have resulted from two possible sources, firstly that the nature of the carbide(s) formed at higher temperature(s) require(s) a higher concentration of alloying elements and carbon content (i.e. high concentration of metal atoms such as Mn & Cr) and/or secondly that Mn is preferentially partitioning to the matrix phase(austenite) due to its intrinsic tendency to stabilize austenite or perhaps a combination of the two(Table 6.33). Thirdly, a considerably altered Vf of MCs ·on heat treating from high temperatures should not be overlooked.

(ii) The said ratio appeared to follow a general trend, though not strictly, namely that it appeared to increase marginally with Cu content (least in C1). The possible reasons are that (a) a carbide with a higher metal concentration is forming and/or (b) an increase in the Cu content(τ- stabilizer) is allowing a larger concentration of Mn to partition to the carbide since Cu is now additionally playing the role of a τ-stabilizer(Table 6.33).

Having discussed the Mn partitioning it would be pertinent to comment upon the partitioning of Cr. The partition ratio $Cr_{carbide}/Cr_{matrix}$ in the as-cast state is 6.5-7.5 somewhat lower than the expected partitioning ratio [Sandoz (S1),(S2)] thereby indicating that the carbides formed incorporates lesser Cr content than normal. This is perhaps due to a part of Cr being replaced by Mn. On heat treating, the ratio increased with temperature/ time for reasons already discussed while considering Mn partitioning, although a consistent trend was not observed. Exception is C2 which showed an initial decrease in ratio followed by increase at high temperatures. On heat treating from 1000°C , 10 hours, the $Cr_{carbide}/Cr_{matrix}$ is larger than what was observed in the as-cast condition thereby implying that the carbide to form is richer in Cr(Table 6.33) and lower in Mn

content as has already been discussed and commented upon. The inference is that the preferred carbides to form would be of the type M_7C_3 and/or M_5C_2. X-ray diffractometric analysis has suggested this to be so and this is duly corroborated by EPM analysis as discussed in the ensuing sections.

The important implications of these observations are that although Mn is considered to be an austenite stabilizer(implying a large partitioning into austenite), its known carbide forming tendency is enabling a larger proportion of it to partition into the carbide phase. This is further made apparent when the partition ratio of a conventional austenite stabilizer like Ni is considered(based on data reported by Sandoz |Sandoz (S2)]. Therefore, in order to ensure that the requisite amount of Mn is available in austenite a substantially larger amount of Mn would have to be added.

Talking about Cu partitioning it is seen that bulk of the Cu partitions into the matrix. This is to be expected in view of its (i) inherent tendency to stabilize austenite and (ii) negligible carbide stabilizing tendency. On raising the heat treating temperature, the amount of Cu in the carbide is negligible. This is again as per expectations and consistent with the behaviour of other graphitizing elements Ni and Si, which

211

are essentially found in the matrix [Sandoz (S1), (S2)]. It may, however, be remembered that the graphitizing tendency of Cu is not as marked as that of either Ni or Si and that it is effective only at higher temperatures and when added in larger amounts.

Having thus discussed the general partitioning pattern, it would now be appropriate to comment upon the nature of the carbides formed in the as-cast condition and the effect of heat treatment on their nature. The observation that both Mn and Cr partition to the carbide phase alongwith Fe makes it evident that the carbides formed are mixed Fe, Mn, Cr type. Based on the element distribution, the MCs forming in C1 in the as-cast state mostly comprise M_3C and M_9C_3. Thus the possible indexing of the M_5C_2 carbide, as revealed through the analysis in the sections 6.1.1.1 & 6.1.1.2(Tables 6.23-6.25) may have to be revised. The observation that the carbides formed contain Fe, Mn, and Cr whereas only Fe and Mn are known to form M_5C_2 type carbide [Kuo (K11)] further suggests that the possible presence of M_5C_2 will have to be conclusively established (Table 6.27).

Similarly the presence of M_7C_3 type carbide in C2 and C3 in the as-cast state is on the expected lines since an increase in Cu content (compositions of C2 & C3) enables a larger

partitioning of Cr into the carbide phase thereby enhancing the tendency to form Cr enriched M_7C_3 type carbide (Figure 6.1, Tables 6.26-6.32).

The identity of the "haloed regions" has been confirmed as a carbide although with a Cr content about 10% less than in the MCs. The formation of such massive carbides has been reported in the literature [Stefanascu (S14)]. Irrespective of the reasons for their formation, such an occurrence reflects upon the heterogeneity of the alloys (Figures 6.1a-d,i,k,l; Table 6.30).

As already appropriately resoned (section 5.2.4.2), the dark etching areas represent those regions within the matrix whose composition differs from the rest of the matrix (Tabe 6.30). Their composition approximates to M_7C_3 type carbide except for the high concentration of Cu and Si. In fact with time these regions would have developed into well formed carbide(s) thereby abridging the two agglomerating carbide regions into a whole mass.

In the light of the above, it may not be out of place to suggest that the DSPs are mostly M_7C_3 and/or M_3C type (Table 6.29, Figure 6.1i). Thus the conclusions arrived at on the basis of x-ray diffractometric analysis regarding the possible

attainment of M_5C_2 have to be modified by excluding its presence. This conclusion is also in agreement with the deductions arrived at in a study involving the transformation behaviour of Cr-Ni in the heat treated condition wherein the formation 'needle shaped' DSPs of the type M_3C has been reported [Laird - II (L1), (L2)]. This further confirms the analysis put forth while analyzing the structures that the needle type DSPs based on their etching characteristics and growth behaviour are in fact carbides and not intermetallics. The observation that part of the DSPs are needle like & partly dispersed may also be differently interpreted to mean that the DSPs are essentially in the form of needles and the DCs observed may in fact represent the 'end view' of the needles that are oriented perpendicular to the plane of observation. This may be considered as an appropriate justification for treating the DSPs and DCs as one entity while carrying out quantitative metallographic studies although in the present investigation the volume fraction of needle type DSPs is rather small.

Finally it becomes incumbent to comment upon the influence of one element on the partitioning of the others into different phases.

Considering now the effect of Cu on the partitioning of Mn, it is seen that Cu is either having little effect or is perhaps

promoting Mn to perform its customary function(of being a τ-stabilizer/carbide former). A somewhat similar effect is observed on Cr partitioning. In fact, as expected, the amount of Cr in the matrix appears reduced(Table 6.26) thereby further confirming that Cu is promoting Cr to perform its usual function of forming/stabilizing carbide(s).

The formation of copper in the as-cast condition(Table 6.23-6.25), although not expected, may be explained by stating that in the as-cast condition, the alloys contain martensitic regions and elemental copper could have been present in those regions. However its formation even in the heat treated condition in the form of Cu enriched regions (Table 6.32, Figure 6.1 f-g) especially on heat treating for higher temperatures is a surprising result since the matrix under these conditions is fully austenitic and Cu has a large solubility in austenite. None the less the result is an important one and its implications could be examined only after a more detailed EPM analysis.

6.2.3 CONCLUDING REMARKS

Based on the above critique, it can be concluded that-

(i) MCs are mostly a combination of M_7C_3 and/or M_3C depending upon the condition/heat treating regime.

(ii) DSPs mostly comprise M_7C_3/M_3C

(iii) Cu is present both in the as-cast/heat treated condition

(iv) the dark etching regions observed on heat treating from high temperature(s) represent regions with an 'alloy concentration' different from that of the matrix. They represent a composition close to an M_7C_3 type carbide but containing large amounts of Cu and Si.

(v) Mn partitioned more to the carbide phase and less to the matrix. This situation was not altered even on heat treating from high temperature(s)

(vi) the distribution of Cr, Si, and Cu was on the expected lines.

A more conclusive and detailed investigation is required to unequivocally conclude upon the absence of M_5C_2 type of carbides. For this reason their indexing has not been deleted while analyzing the x-ray diffractometric data(Tables 6.23-6.25).

6.3 THERMAL ANALYSIS

Differential thermal analysis comprised (i) assessment of the critical/transformation temperatures, and (ii) compilation of the thermogravimetric (TG) data, and (iii) modelling of the TG data, carried out to a limited extent. The data thus obtained have been summarized in the Tables 6.34-6.37 and in the Figures 6.2-6.3. Results have been discussed in the following sections.

6.3.1 RESULTS

6.3.1.1 CRITICAL/TRANSFORMATION TEMPERATURES

(i) First transformation occurred 540-575°C(Table 6.34).

(ii) The second transformation similarly occurred in the temperature range of 960-980°C(Table 6.34).

(iii) In C1 and C2 third transformation was seen to occur at 740-760 °C (Table 6.34).

(iv) C1 also revealed a phase change occurring at 900°C.

6.3.1.2 DTA

(i) For the first transformation (540-575°C), DTA values were negative and were in the range of 3.2-4.6μV(Table 6.35).

(ii) For the higher transformation (960-980°C), DTA values were positive and ranged from 10.0-18.0μv (Table 6.35).

(iii) For the transformation observed in C1 and C2 only (740-760°C), the DTA value was positive for C1 and negative for C2 (Table 6.35).

(iv) For the transformation (900°C), occurring only in C1, the DTA value was positive and 3.4μV(Table 6.35).

6.3.1.3 THERMOGRAVIMETRIC STUDIES

This data, summarized in the form of plots between %TG as a function of temperature, are shown in the Figures 6.2-6.5 and

217

Tables 6.36-6.37(Figure 6.5 summarizing the overall information).

From the figures, the following inferences were drawn:

(i) %TG increased very slowly with an increase in temperature. This was followed by an exponential increase on raising the temperature further.

(ii) The nature of these plots was a function of the microstructure.

(iii) In the as-cast state, the weight gain was nearly a constant up to approximately 600°C. %TG corresponding to this condition was a minimum for C3 followed by C1 & C2. A steep increase in the %TG was observed on moving from 900°C to 1000°C. In fact up to 800°C, the increase in %TG with temperature was gradual(Figure-6.5).

(iv) Taking an overall view, an increase in the Cu content accounted for a decrease in %TG at least in the as-cast condition i.e. a higher Cu content was conducive to improving high temperature oxidation resistance.

6.3.2 DISCUSSION

The DTA studies proved useful in substantiating the structural observations reported earlier(section 5.1.2). Such a study was expected to prove helpful in resolving some of the existing inconsistencies and in providing additional information

on the possibility of employing the experimental alloys for high temperature applications. The least that was expected from the study was by way of information on the transformation/critical temperatures.

6.3.2.1 CRITICAL/TRANSFORMATION TEMPERATURE(S)

The first set of transformation temperature(s) occurring at 540-575°C evidently represent the $\alpha \rightarrow \tau$ transformation in the experimental alloys Evidently, those regions which were α/α' would transform. A near similarity in the DTA values suggests that the three alloys have roughly similar τ forming tendency thereby suggesting that an increase in the copper content has little effect on the τ stabilizing tendency. This deduction belies the normally held view since Cu is known to be a τ-stabilizer and should prove effective in doing so since another austenite stabilizer is already present. Moreover, the $\alpha \longrightarrow \tau$ transformation temperature has been considerably reduced due to the presence of 10% Mn(common to all the alloys). A more plausible explanation is that this temperature represents the formation of FeO through a process of internal oxidation. In the presence of Mn,Si,P,&Si, the formation of FeO is mildly exothermic as has been observed in the present study for alloys both in the as-cast and heat treated conditions.

219

The next important set of transformation temperatures (960-980°C) evidently represents carbide transformation which is duly suggested by optical metallographic studies(Figures 5.22-5.42) and confirmed through x-ray diffractometric analysis(Tables 6.23- 6.25). The possible transformation in the temperature range 960-980°C will comprise the (a) precipitation/ growth of carbides constituting the DSPs(M_3C and/or M_7C_3) and (b) conversion of M_3C/M_5C_2(?) into the higher temperature carbide forms. While saying so it should also be remembered that the magnitude of the peak in the DTA plot does suggest that more than one transformation is occurring perhaps involving a change of state otherwise it would be difficult to account for the pronounced peak (Figures 6.2-6.4) [Rao (R5)]. At the same time it is equally true that optical metallography does not in any way suggest a change of state(formation of a liquid phase). A close scrutiny of the data summarized in the Tables 6.23-6.25 and the aforesaid discussion supplementing these observations reveal th t the DTA data is in fact representing a carbide transformat on involving a change over from M_3C to M_7C_3 via the formation of a transition carbide of the type M_5C_2.Although the reasons for the occurrence of a third transformation in C1 are not clearly understood, it is quite likely that the eventual carbide transformation observed at 960-980°C may have initiated in C1 at

~ 900°C.

Although an attempt has been made to arrive at definitive deductions on the basis of DTA results, perhaps a more rigorous experimentation would have enabled doing so with greater certainty. Such an experimentation would comprise (i) employing different heating rates starting from the lowest value e.g. of the order of 0.1°C/min., (ii) plotting out of the initial and peak transformation temperatures, (iii) extrapolating the initial and peak transformation temperatures to a heating rate equivalent to zero to obtain the equilibrium transformation temperatures, and (iv) calculation of heat of reaction based on the peak area finally culminating in the calculation of heat capacities of the reactants and that of the products [Schute (S4), Mackenzie (M1), Kofstad (K1)]. It is suggested that the DTA studies be more rigorously carried out in order to arrive at precise information on the transformation behaviour of the experimental alloys.

6.3.2.2 THERMOGRAVIMETRIC STUDIES

Thermogravimetric studies proved helpful in drawing inferences regarding the usefulness of the experimental alloys for high temperature applications. Since, the basic aim of the study was to optimize the microstructure for obtaining the best in terms of corrosion and heat/oxidation resistance and

deformation behaviour, even the as-cast microstructure was expected to respond favourably when exposed to high temperature. Therefore to begin with, its high temperature behaviour was investigated to arrive at some initial data especially with regard to the effect of copper content. It was reasonable to do so since "alloy design" had been aimed at stabilizing the high temperature microstructure to room temperature in as large a measure as possible.

From a perusal of the thermogravimetric data(Figure 6.5 & Tables 6.36-6.37), it emerges that the TG data for as-cast micro-structure has two distinct regions, (i) up to 600°C and (ii) beyond 600°C and extending up to 1050°C. The first of these is characterized by a very small and more or less uniform increase in %TG suggesting the usefulness of as-cast structure up to 600°C. An equally important aspect is that till a temperature of 600°C the behaviour of the alloy C3 was superior to the other two (though comparable with C1), at T > 600°C the behaviour varied significantly in the sense that alloy C3 was found to be much superior than the other two behaving similarly. The observation that the higher the copper content the lesser the weight gain is true for high temperatures (≥ 700°C) and partially true at lower temperatures (C1 better than C2 though C3 is best). This difference in the behaviour can be attributed to the presence of

more amount of MCs (predominantly M_7C_3 type) at lower temperatures. M_3C was better indexed in C1 and C2 in Comparison to C3 (Tables 6.23-6.25). Presence of M_3C is disadvantageous from the point of view of high temperature oxidation resistance because (i) to begin with it has a high coarsening tendency and (ii) its transition to a higher temperature form. A temperature of 600°C could be considered as representing the transition stage. At temperature ≥ 900°C, the high temperature behaviour is being governed by the volume fraction of the MCs(the nature of carbide being mostly M_7C_3 and stability of matrix (austenite) which is controlled by the Cu content. The larger the Cu content the better will be the stability of austenite.

To understand the interrelation, if any, between the TG data and the DTA results, the data summarized in the Tables 6.36-6.37 and Figure 6.5 were reexamined. From this comparison, it also emerges that the sharp increase in %TG may be related with the susceptibility to carbide transformation; the more marked the susceptibility the less useful the alloy. This can be explained by stating that an alloy susceptible to carbide transformation essentially exhibits proneness to configurational changes at the atomistic level. And this would lead to enhanced oxidation. Thus the key aspect would be to employ heat treatments to exclude such

transformations.

Before concluding it would be pertinent to record that a more comprehensive understanding of the high temperature behaviour would have emerged if thermogravimetric studies were carried out on alloys in the heat treated condition. None the less on the basis of the studies carried out (data not reported) it can be concluded that the basic parameters controlling the high temperature performance are (i) the stability and volume fraction of austenite, (ii) volume fraction of the "high temperature" carbide forms M_7C_3/$M_{23}C_6$/M_5C_2, and (iii) presence/absence of "low temperature" carbide forms. Based on the quantitative metallographic data, the most useful microstructures in the as-cast condition may comprise a minimum of 15-20% carbide and balance austenite (in the present alloys the amount of carbides is higher). This situation changes when heat treated micro- structures are considered as the volume fraction of carbides reduces. This will certainly not be useful from the point of view of high temperature properties in the sense that the strength will reduce but the absence of susceptibility to "carbide transformation" is advantageous. Thus if we could attain all the merits of the 'high temperature heat treated' microstructure and yet retain a larger volume fraction of the MCs, that would be ideal. The existence of lower

temperature carbides is not desirable since their effectiveness is greatly reduced at (high) temperatures at which they could coarsen and/or may undergo transformation, either of which is undesirable.

Finally, the occurrence of a phase transformation during heating at or below the temperature at which the alloy is intended to be used would adversely affect high temperature performance as the base/expected microstructure is prone to a change in its configuration at the atomistic level i.e. it is susceptible to enhanced rate of migration of atoms/material flow.

6.3.3 MODELLING OF THE TG DATA

The discussion contained in the Section 6.3.2.1 essentially dealt with the high temperature response of some selected microstructures and of the possible impact of various transformations, occurring during heating/treating, in affecting the overall high temperature performance. Having done so, it would now be appropriate to look into modelling aspect of the TG data. In order to do so, it would be necessary to examine the processes involving high temperature oxidation per se and arrive at the possible rate laws relevant to the present study, which would eventually form the basis for modelling.

Oxidation of metals can be expressed by a simple chemical reaction as

$$aMe + \frac{b}{2} O_2 \longrightarrow Me_a O_b \qquad \qquad \dots(6.2)$$

However, the reaction path and the oxidation behaviour of a metal may depend on a variety of factors, and reaction mechanism(s) may as a result prove complex.

The initial step in the metal-oxygen reaction involves the adsorption of gas on the metal surface. As the reaction proceeds, oxygen may dissolve in the metal forming an oxide on the surface either as a film or as a separate oxide nuclei. Adsorption and the initial oxide formation are both functions of surface orientation and condition, concentration of crystal defects at the surface, and impurities in both the metal and the gas [Kofstad (K1)].

The surface oxide separates the metal from the gas. This oxide may either be in the form of thin tenacious film or as a porous oxide scale.

For a particular metal, the reaction mechanism is a function of the pre-treatment and surface condition, temperature, gas composition and pressure, and elapsed time of reaction. Looking to the possibility of a large variation in the properties of

different metals and alloys and their oxides, a number of theories are needed to describe the oxidation behaviour of metals [Kubaschewski(K3), Hauffi (H3), Benard (B7)].

A detailed understanding of this phenomenon requires knowledge of reaction rates and kinetics, the temperature and oxygen pressure dependence of the reaction, the composition, structure, and growth mechanism of the reaction products.

Rate equations describing oxidation may be classified as logarithmic, parabolic, and linear. These are discussed in detail elsewhere [Kubaschewski (K3), Hauffi (H3), Benard (B7), Evans (E3), Loviers (L6), Webb (W5), Haycock (H4)] and are not relevant to the present study because temperature dependence of oxidation behaviour alone has been studied.

Numerous oxidation reactions have shown empirically that the temperature dependence of oxidation rate constants at a constant ambient oxygen pressure obeys an Arrhenius-type equation

$$k = k_0 \exp(-Q/RT) \qquad \qquad \ldots(6.3)$$

where Q is the activation energy commonly given in cal/mole, R is the gas constant(1.986 cal/$^\circ$K mole), and the T the absolute temperature. The pre-exponential factor, k_0, is within experimental accuracy, usually found to be independent of

temperature. Using Equation 6.3, the activation energy Q is determined by plotting $\log_{10} k$ as a function of $1/T$, in which case the slope of the curve is given by $Q/2.303R$. The rate constant at different temperatures is commonly determined from isothermal measurements, but may also be determined from a single run under conditions of linearly increasing temperature [Kofstad (K2)].

Nucleation and growth phenomena may give rise to unusual oxygen pressure-dependence of the process of oxidation [Sewell (S5), (S6); Rahmel (R1)]. Considering oxidation of Fe as an example, Fe_3O_4 is initially formed on the surface (FeO is unstable below $570°C$), and Fe_2O_3 is subsequently nucleated in the Fe_3O_4 surface. When Fe_2O_3 has grown to form a continuous layer, the oxidation rate is substantially reduced.

A scrutiny of the Figure 6.5 reveals that although the %TG varies exponentially with temperature, the plot has two distinct parts, the nature of variation in one being opposite to that of the other. The first part (from ambient temperature to $200°C$) can be represented by an asymptotic curve as

$$\%TG = A1'(\exp^{-A2/T} - 1) \qquad \qquad ...(6.4)$$

and the second part can be represented as

$$\%TG = A1 + A2(\exp^{-A3/T}) \qquad \qquad ...(6.5)$$

where, A1', A2', A1, A2, and A3 are constants, and T is temperature in ˚K.

The %TG increase in the first part is very small(~2%) compared to the overall increase of up to (18-25%) attained at highest heating temperature. It was therefore, felt appropriate to neglect· the former in arriving at the proposed model. As before multi-variable nonlinear constraint optimization technique [Himmelblau (H10), Mangasarain (M4)] was employed to do so.

The correlations thus obtained are summarized as follows:

Alloy C1   %TG = 2.2761 + 7999.65 exp(-7929.25/T)   ...(6.6)

Alloy C2   %TG = 2.5190 + 7426.91 exp(-7999.98/T)   ...(6.7)

Alloy C3   %TG = 1.9690 + 6046.54 exp(-7999.98/T)   ...(6.8)

The %TG was calculated from the aforesaid correlations and a plot of predicted %TG as a function of temperature obtained (Figures 6.6). The predicted %TG values lie very close to the experimentally determined values thereby indicating the validity of the models developed.

DEFORMATION & CORROSION BEHAVIOUR

7.1 INTRODUCTION

Having established the transformation characteristics of the alloys and carried out the phase analysis and phase identification with a reasonable accuracy and certainty, it becomes essential to carry out an in depth analysis of the deformation and corrosion behaviour as this alone would decide as to how far the objectives outlined in the introduction/alloy design have been achieved. While the deformation behaviour was assessed through compression testing, the corrosion characterization has been carried out with the help of weight loss studies.

7.2 EFFECT OF HEAT TREATMENT ON THE DEFORMATION BEHAVIOUR

As already stated, the deformation behaviour was assessed through compression testing and the data have been reported in Tables 7.1-7.3.

Apparently, the data thus summarized did not conform to a specific trend. However it can be attributed to the fact that some of the specimens might have fractured prematurely due to the existence of pipe not visible outwardly. This problem was resolved through a normalization process carried out in the

following manner-

(i) by modelling the hardness-strength interrelation on a basis

adopted by Kumar [Kumar (K6)].

(ii) by computing the predicted value(s) of CS based on the

above model, and

(iii) by indirectly computing the likely experimental values on

the basis of their differing from the predicted values by

±15%.

7.2.1 MODELLING OF THE DEFORMATION BEHAVIOUR

Hardness is a very useful measure of the mechanical

properties(deformation behaviour) of materials. Therefore, it is

regarded as a quick yet a reliable measure of strength. Normally

higher the hardness the larger is the UTS/CS and smaller the %

elongation value. In ferrous materials(steels) hardness and

tensile strength are related empirically through a conversion

factor

$$5 \text{ VHN}_{30} \equiv 1 \text{ tsi UTS} \equiv 15.5 \text{ MPa}$$

A similar empirical law is not expected to be obeyed in cast

irons in general and white irons in particular because, as

engineering materials, they are a class apart from steels due to

their brittleness and due to a generally complex microstructure.

An attempt was, therefore, made to examine the possibility of

establishing a quantitative relation between hardness and deformation behaviour in the experimental alloys. The information thus generated was expected to provide a back up to the mathematical modelling work being actively pursued.

7.2.1.1 INTERRELATION BETWEEN COMPRESSIVE STRENGTH AND HARDNESS

To begin with CS was plotted as a function of hardness. As no definite relationship emerged, it was decided to plot CS/H as a function of hardness. On doing so a second order polynomial functional relationship between the two parameters emerged and therefore hardness can be represented as

$$R = A1 + A2 (H) + A3 (H)^2 \qquad\qquad ...(7.1)$$

where R = CS/H,

H = hardness, HV_{30},

A1, A2 and A3 are constants.

The constants A1, A2, and A3 were computed as before and the correlations thus obtained are :

Alloy C1 : $R = -11.58 + 0.0667H - (0.6926E-04)H^2$ ...(7.2)

Alloy C2 : $R = 36.92 - 0.1299H + (0.1227E-03)H^2$ ...(7.3)

Alloy C3 : $R = 24.98 - 0.0629H + (0.4240E-04)H^2$ ...(7.4)

CS values for the experimental alloys were computed on the basis of above models. On comparing them with the experimentally

determined values, it emerged that the difference in most cases does not exceed ±10%(Table-7.4). In some instances the experimental and the predicted values differed by a larger margin which might be due to casting defects present in the test specimens.

7.2.2 EFFECT OF HEAT TREATING TEMPERATURE/TIME

(i) For the alloy C1 (2 hours soaking period), the CS initially increased over that in the as-cast state on heat treating from 900°C (Tables 7.1 & 7.4). A further increase in the temperature upto 1050°C lead to a decrease in the CS. The predicted values did not follow the same trend, the decrease was negligible and for all practical purposes the variation could be considered as being linear.

A similar trend was observed on heat treating for 6 hours soaking period except that the predicted values of CS followed a pattern in reverse. As stated earlier, the magnitude of increase/decrease was small and it could well be stated that heat treating has had little effect i.e. the expected benefits have not accrued (Table 7.4).

On increasing the soaking period to 10 hours there was a decrease in strength on raising the temperature from 1000 to

1050°C; the predicted values followed a similar trend.

(ii)   In alloy C2, CS increased significantly over that in the as-cast state on heat treating from 900°C for 2 hours soaking period. An increase in the heat treating upto 1000°C had an adverse effect followed by an increase in the strength on heat treating from 1050°C. The predicted values followed a decreasing trend (Tables 7.2 & 7.4).

For the 6 hours soaking period CS decreased continuously with temperature although the predicted values remained more or less unchanged.

At 10 hrs soaking period, the variation in CS with temperature followed a trend similar to the one observed at 2 hrs soaking period. The predicted values of CS also followed a similar trend.

(iii)   In alloy C3 (6 hrs soaking period), the CS initially increased on raising the temperature from 900°C to 950°C. This was followed by a significant decrease in CS on heat treating from 1000°C. Contrary to C1 and C2 an increase in CS was observed on raising the temperature to 1050°C. The predicted values exhibited a continuously increasing trend.

On raising the soaking period to 10 hrs, CS to begin with was low, it increased with temperature and became a constant. The predicted values, although revealing an increasing trend with temperature, showed a marked increase on raising the temperature from 1000°C to 1050°C. The experimentally determined values had remained unaltered on heat treating from this temperature range.

7.2.3 DISCUSSION

The aforesaid data can be suitably interpreted on the basis of the initial volume fraction of MCs, the effect of temperature/ time in influencing the formation and morphology of DSPs and their effect in decreasing the volume fraction of MCs. That this contention is true can be judged by recalling that the property changes are being by and large controlled through the aforesaid structural changes (the partially martensitic matrix on heat treating from 800° and 850°C not withstanding.

Before setting out to explain the trends for the 2 hrs, 6 hrs and 10 hrs soaking periods, which are analysed in the form of plots summarized in the Figures 7.1 to 7.3 (some of the plots contain 3 points). It may be mentioned that % strain has not been reported since it could not be determined with accuracy and certainty for all the heat treatments.

DSPs are expected to strengthen and also embrittle the material somewhat especially when their morphology is adverse (needle like/platy). This is applicable at the lower heat treating temperatures and soaking periods. With an increase in time, their embrittling response is expected to reduce because their volume fraction reduces as a result of coarsening and also because the DSPs then predominantly comprise DCS. However on raising the temperature at either of the soaking periods, embrittlement reduces because the Vf of DSPs and MCs is reducing and the morphology of latter is assuming favourable configurations. With an increase in temperature the DSPs/DCs are less relevant and therefore the overall properties would be governed by the volume fraction, distribution and morphology of MCs as the matrix in combination with the MCs/DCs is constituting a composite comprising MCs and DSPs upto 950°C and mostly MCs at T > 950°C. Based on this analysis, the data summarized in the Figure 7.1 to 7.3 can be reasonably well understood; only the trends would be analysed in the following section.

In C1 at 2 hours (Figure 7.1) soaking period, a CS higher than in the as-cast state (900°C) is due to the formation of an austenitic matrix and the presence of DSPs mostly as DCs which would compensate for the reduced strengthening response due to a

decrease in the volume fraction of MCs (Figure 5.25). On raising the temperature to 1000°C the volume fraction of DSPs decreases and no needle type structure is present (Figure 5.27). This alongwith a reduced volume fraction of MCs and a higher stability of the austenitic matrix accounts for an increase in CS. However on further raising the temperature to 1050°C, the expected improvement in CS for reasons already stated has not occurred due to the formation of degenerate structure (dark patches) and aligned MCs giving rise to an appearance as though MCs are acquiring afresh a platy/needle type morphology (Figure 5.28). It may be mentioned that absence of DSPs/DCs, a reduced Vf of MCs and a higher stability of austenite should have proved helpful in enhancing CS. However, this has not happened and the adverse features have prevailed. At 10 hrs soaking period, the overall CS values are lower than the ones attained on heat treating for 2 hrs. Furthermore they appear to decrease with temperature. This is not easy to comprehend. Since a similar situation exists at 6 hrs soaking period, it may be inferred that the adverse microstructural features for the 6 hrs and 10 hrs soaking period (heat treating temperatures 1000° & 1050°C namely the linking up of platy carbides and microstructural degeneracy are having a dominant effect (Figures 5.27 - 5.28).

In alloy C2 at 2 hrs soaking period the best in terms of CS has occurred at a lower temperature (900°C) compared to C1 (Table 7.4). this is followed by a decrease on heat treating from 950° and 1000°C due to inhomogeniety of the matrix and to the existence of a degenerate microstructure (Figure 5.33 - 5.34). An improvement in CS on heat treating from 1050°C but not to the extent one would have expected can be explained on a basis similar to that putforward earlier to analyse the data observed in C1 (Table 7.4). On increasing the soaking period to 10 hrs, the overall CS values are higher than the ones attained at 2 hrs soaking period and increase with an increase in the heat treating temperature thereby implying that the favourable structural features are dominating and that the overall effect of the adverse microstructural features is reducing (Table 7.4, Figures 5.33 - 5.35). This would also explain why the alloy C2, overall and especially on heat treating at 10 hrs soaking is ataining higher CS than C1.

This being so, the better overall CS attained in C3 over that in C2 can be easily explained on the basis of an inter-play between the favourable and unfavourable microstructural changes as discussed earlier. It may be worth noting that the best CS has been attained in C3 on heat treating for 10 hrs at 1050°C when the volume fraction of MCs is the least. This has been made

possible due to a favourable morphology of MCs, minimum micro-structural degeneracy, a reasonably uniform distribution, a good compatibility of MCs with the matrix (Figure 5.42). The favourable changes on transiting from the composition of C1 to C3 could be attributed to an increase in the Cu content.

7.3 CORROSION STUDIES

The results reported thus far dealt with the transformation behaviour of the experimental alloys arrived at on the basis of hardness measurements, optical metallography, X-ray diffraction, EPMA, and compression testing. Having achieved this target, it was appropriate to characterize the alloys for their corrosion behaviour. Corrosion behaviour was studied with the help of weight loss method as it is deemed to be reliable method as the results are reproducable. The data thus obtained have been summarized and discussed in the following sections.

7.3.1 ANALYSIS OF DATA BASED ON "WEIGHT LOSS" STUDIES

7.3.1.1 WEIGHT LOSS DATA :

Weight loss were studies were carried out on as-cast/heat treated specimens of the experimental alloys as per the relevant ASTM specifications. The data presented in the Tables 7.5-7.6 revealed that-

(a) The corrosion rate even in the as-cast state was reasonably good, it being the maximum in C1 and minimum in C3.

(b) On heat treating from 'lower temperatures, the corrosion rate increased over that in the as-cast state up to a particular heat treating temperature/time and began decreasing there after.

(c) The adverse effect persisted up to 900°C and for lower soaking periods for all the experimental alloys. However, situation was quite encouraging for 10 hours soaking period at 900°C where corrosion rate was found to be lower than that observed in as-cast condition.

(d) Although the beneficial effect of increasing the heat treating temperature in improving corrosion resistance was in evidence as early as at 900°C, 10 hours heat treatment (marked in C1 and C2 & marginal in C3), a tangible effect set in only on heat treating from 1000°C. The magnitude of improvement was proportional to the amount of copper present(minimum in C1 and a maximum in C3) and soaking period.

(e) This is duly reflected in the alloy C3 attaining the least corrosion rate & marginally better than that attained in C1 or C2.

The data contained in the Tables 7.5-7.6 could be looked at differently on the basis of the plots summarized in Figures 7.4-7.6. The plots besides revealing a second order variation between corrosion rate and temperature, revealed the relative usefulness of microstructures generated in the experimental alloys, in resisting corrosion e.g. in all ivestigated alloys the microstructure attained on heat treating at 900°C(2 hours) had an adverse effect & it(adverse effect) decreased gradually by increasing the heat treating temperature/time. The adverse effect of this microstructure however was not observed at the 10 hour soaking period. The plots further revealed the usefulness of the following structures in resisting corrosion:

C1   --   microstructures at 10 hours soaking period,

C2   --   microstructures at 10 hours soaking period,

C3   --   microstructures at 2 and 10 hours soaking periods

7.3.1.2. NATURE OF CORRODED SURFACES

The corroded surfaces on being examined under a scanning microscope revealed absence of pitting and or graphitic corrosion. The attack was uniform and even after the completion of the test, the specimen surfaces retained a fair amount of polish revealing negligible surface attack. The corrosion product was non-adherent. The photographs merely showing the surface

topography of the polished specimens have not been included.

7.3.1.3. DISCUSSION

The weight loss data give a substantial and authentic information on the corrosion behaviour of different micro-structures. In a general sense it reveals reasonably good corrosion resistance in the as-cast condition, its marginal deterioration, at best, on heat treating up to a certain temperature(900°C) and 2 hrs for each alloy, the maximum deterioration occurring at a specified heat treatment to be followed by a substantial improvement in corrosion resistance on heat treating from high temperatures (1000/1050°C) preferably on soaking for larger periods. This is indeed a welcome trend because in the temperature range of 800- 950°C needle or plate shaped DSPs as well as DCs have formed in all the three alloys(Figures 5.23-5.25, 5.30-5.32, and 5.37-5.39). That the corrosion rate on heat treating from temperatures within 'this range' is not much different from that in the corresponding as-cast state reveals that the adverse morphology/distribution of the DSPs & the alignment of DCs and MCs (Figures 5.23-5.25, 5.30-5.32, and 5.37-5.39) have had a minimal adverse effect on corrosion behaviour thereby reflecting favourably upon the τ/DSP & τ/MC couple in resisting aqueous corrosion in 5% NaCl solution. In fact the data summarized in the Table 7.6 and Figures 7.4 -

7.6 further indirectly indicate that the DSPs are of a similar character as the MCs i.e. the DSPs & DCs should in fact be either M_7C_3 and or M_3C type carbides. It is surmised that the possible formation of M_5C_2 may have adversely affected the corrosion behaviour more than what is reflected by the data summarized in Table 7.6 due to its monoclinic structure inducing enhanced incompatibility between second phase and the τ-matrix.

Having said so it would be pertinent to examine the microstructures/heat treatments which have given rise to a substantial increase in corrosion rate.

A careful perusal of the microstructures for the 900°C, 2 hrs heat treatment for the experimental alloys (Figures 5.25, 5.32 & 5.39) revealed that the features common to the three alloys which could have affected corrosion resistance adversely are (i) unevenness of the matrix(matrix heterogeneity), and (ii) bunching & alignment of carbides MCs & DCs (more apparent in C2 and C3). Interestingly the other parameters used to define distributional heterogeneity (Tables 5.99-5.60) apparently do not show the aforesaid microstructures in a poorer light, except the distribution heterogeneity associated with DCs in C3, thereby suggesting that chemical heterogeneity(associated with the matrix) may be the dominant factor in adversely affecting the

corrosion resistance. This analysis also suggests that the presence of DSPs with unfavourable morphology appeared to have a minimal adverse effect whereas the matrix unevenness (heterogeneity) appeared to have a more dominant effect in adversely affecting corrosion resistance. On the other hand unfavourable morphology of the DSPs has a definite adverse impact on the deformation behaviour of the alloys as already discussed in section-6.2.3. This explains the corrosion data on heat treating from temperatures up to 950°C.

On heat treating from 1000°C, the three alloys showed a marked improvement in corrosion resistance due to the elimination of DSPs, the MCs attaining spherical/hexagonal morphologies (favourable), 'rounding off' at the edges of MCs, and due to a reduction in the Vf of MCs. Alloy C3 with the highest Cu content (at 2 hours soaking period) attained a marginally lower corrosion rate than either C1 or C2 due to its lowest Vf of MCs, a more stable τ, and a better morphology of MCs. These beneficial effects are further accentuated at 10 hours soaking period leading to considerable improvement in corrosion resistance in C1 & C2. However the beneficial changes are attained, in general, on heat treating from 1050°C leading to the attainment of minimum corrosion rates in the experimental alloys(Table 7.6, Figure

7.4-7.6). It is of significance to note that in spite of a heterogeneity arising out of the formation of 'degenerate' dark regions around MCs and a general unevenness of the matrix due to reprecipitation of DCs(attributed to enhanced graphitizing action resulting from an increase in the Cu content from 1.5% in C1 to 5% in C3), the alloys are attaining very low corrosion rates and yet not exhibiting any kind of localized attack. It is evident that in the absence of the above mentioned heterogeneities, the alloys would have exhibited still lower corrosion rates. The discussion would imply that to reduce heterogeneity the process(es) responsible for accelerating different transformations (already discussed) have to be contained. There is thus a need to optimize the Cu content keeping in mind the seemingly contradictory effects it is producing namely (i) the transformation 'accelerating effect' promoting a reduction in the amount of second phase(partly beneficial & partly retrograde), (ii) increasing the Cu content of the matrix thereby improving corrosion resistance(beneficial), and (iii) microstructural degeneracy/heterogeneity that is being created due to an enhancement in the transformation kinetics (retrograde).

The SEM examination carried out to a limited extent none-the-less is very encouraging, reaffirms the findings of Jain, Kumar, and Rao, Patwardhan & Jain [Jain (J2), Kumar (K6),

Rao (R5)] regarding the absence of pitting, graphitic corrosion, and the nature of attack being 'uniform dissolution'. The retention of mirror finish on the specimen surfaces even in the corroded condition is a clear indication that some kind of passive layer is perhaps forming. This is concluded from the observation that the corrosion product is non-adherent and 'falls off' merely on shaking the specimen in the aqueous media.

The corrosion rates attained in the experimental alloys are substantially better than the ones reported by Jain [Jain (J2)] in the Fe-Mn-Cr-Cu alloys containing 7.5% Mn & up to 3% Cu. The deformation behaviour of the presently investigated alloys has already been adjudged to be promising. On the strength of these observations the key elements of the alloy design, outlined in the Chapter III, stand vindicated.

Corrosion rates attained on heat treating from higher temperatures are comparable or better than the ones attained in standard Ni-Resist(both flake & S.G. type) compositions being very extensively used under marine conditions. Incidentally the strength of the Ni-Resist compositions is approximately half of that obtained in the experimental alloys. These observations may be regarded as the highlights of the present study with major technological fall out. This aspect has been considered in the

next chapter, in detail, in the section dealing with general discussion.

7.4 MODELLING OF THE CORROSION BEHAVIOUR

An analysis of the corrosion data in the previous section reveals how the different microconstituents influenced corrosion behaviour. Excluding the matrix to begin with, their effect depends upon their nature and size, shape and distribution. When the matrix is also considered, its characteristics (crystal structure and stability) and difference in the electro-chemical potentials between the matrix and the constituents also assume significance. Interestingly, most of the correlations have been qualitative in character. Any effort aimed at modelling the corrosion behaviour will have to incorporate the above said aspects.

7.4.1 BACKGROUND INFORMATION

The first effort in this regard was made by Jain and Patwardhan [Jain(J2); Patwardhan(P4),(P6)] who attempted to correlate corrosion rate with the microstructural features comprising austenitic matrix, massive carbides and dispersed carbides. They selected heat treatments carried out at 900 & 950°C primarily because the different alloys constituting the study attained nearly constant hardness values at these

temperatures. Whereas the hardness was more or less independent of the soaking period, the volume fraction of MCs & DCs varied. It was felt appropriate to examine the methodology adopted by him before enlarging upon the ideas conceived in his work reported recently by Patwardhan & Jain [Patwardhan (P4),(P6)].

It was conceived that the CR could be expressed as a function of different parameters namely,

CR ≈ f(austenite Vf/ stability)

CR ≈ f(Vf of MC)

CR ≈ f(Vf of DC)

CR ≈ f(distribution of the DC)

or   CR ≈ F [(Vf/stability of τ).(Vf of MC).(Vf of DC).(distribution of DC)]   ....(7.5)

To begin with, the last term was excluded and the volume fraction of MCs & DCs was combined into a single term to develop the initial stage model. This was justified on the assumption that since the second phase in general would enhance CR, their overall effect can be cumulated into a single factor.

From the experimental data it was concluded that the functional relationship interrelating corrosion rate with the total volume fraction of carbides(VCb) can be represented by a second order polynomial :

$$CR = A1 + A2(VCb) + A3(VCb)^2 \qquad \qquad ...(7.6)$$

where VCb = total volume fraction of MC + DC

The contribution of the second phase, i.e. the role of dispersed carbides, was included in the above expression by incorporating a factor based on the number of particles, NOP. This led to the following expression :

$$CR = [A1' + A2'(VCb) + A3'(VCb)^2](NOP)^{A4'} \qquad ...(7.7)$$

The constants A1', A2', A3', and A4' were calculated by using the multi-variable constraint optimization technique [Himmelblau (H10), Mangasarain (M4)] and the final equations are:

Alloy C1:

$$CR = (19.982-0.37157(VCb)+0.02125(VCb)^2)(NOP)^{-0.26838} \qquad ..(7.8)$$

Alloy C2:

$$CR = (12.316-0.26605(VCb)+0.00652(VCb)^2)(NOP)^{0.22482} \qquad ..(7.9)$$

Alloy C3:

$$CR = (13.354-0.45377(VCb)+0.01147(VCb)^2)(NOP)^{0.23459} \qquad ..(7.10)$$

Through a suitable analysis involving the effect of two factors in contributing to corrosion, it can be shown that the model is neither physically consistent nor theoretically justifiable since NOP do not truly represent the DC and that the

constants were calculated without adequately understanding the physical implications of the their effect on the corrosion rate. Further the effect of DCs was getting considered twice as it figured as a part of VCb and again as NOP. This was also observed by Jain and Patwardhan [Jain (J2), Patwardhan (P4), (P6)]. Therefore further stress was laid on developing models interrelating the corrosion behaviour with massive second phase and dispersed second phase. Thus the two models developed were CR vs VMC/NOP and CR vs VMC/DF.

Kumar's (Kumar (K6)] work reiterated that the VMC-NOP and VMC-DF models were a satisfactory representation of the corrosion behaviour of the alloys developed. Of the two models, the former emerged as a more effective representation of the corrosion behaviour, some what surprisingly, although his and Jain's [Jain (J2)] studies had convincingly demonstrated that DF was a far better representation of the DCs than the NOP. Through 3-D plotting the idea of 'microstructural optimization' was mooted which proved useful in assessing what best to expect in terms of properties from a given composition. The method to arrive at the optimal minimal values of MC, DF/NOP to obtain the best in terms of performance was also indicated. This enabled optimization of the heat treating parameters to be carried out. Finally the idea of developing a 'unified model', wherein a single model could

predict the corrosion behaviour of all the experimental alloys, was also mooted (Kumar (K26)).

It was decided to expand upon the ideas initially proposed by Jain and Kumar [Jain (J2), Kumar (K6)] and to arrive at a rationalized assessment of the modelling of the corrosion behaviour of the alloys being presently investigated. It was also proposed to compare the data presently obtained with that reported by Kumar [Kumar (K6)] so that a considered appraisal of the state of the art(of this new area) was made possible.

7.4.2 MODELLING OF THE CORROSION BEHAVIOUR OF THE EXPERIMENTAL ALLOYS

7.4.2.1 THE VMC-NOP MODEL

The basis for this model is the qualitative formulation represented by equation (7.5)

$$CR \approx F \ [(Vf/stability\ of\ \tau).(Vf\ of\ MC).(Vf\ of\ DC).(distribution\ of\ DC)] \qquad ....(7.5)$$

As proposed earlier [Jain(J2), Kumar(K6)], the effect of the parameter Vf/stability of τ was considered as constant to begin with so that the equation could be rewritten as

$$CR\ \alpha\ F\ [.(Vf\ of\ MC).(Vf\ of\ DC).(distribution\ of\ DC)]\ ...(7.11)$$

From the experimental data, it was considered that relationship between CR & Vf of MCs could be represented by a

second order polynomial

$$CR = A1 + A2.VMC + A3.(VMC)^2 \qquad \qquad ...(7.12)$$

The role of dispersed second phase in influencing corrosion was considered by incorporating the total number of particles (NOP) into the equation 7.12, which now assumes the form

$$CR = (A1 + A2.VMC + A3.(VMC)^2)(NOP)^{A4} \qquad \qquad ...(7.13)$$

The constants A1, A2, A3, and A4 were calculated by the nonlinear optimization technique permitting the constants to vary over a large unlimited range. The models arrived at are

Alloy C1:

$$CR = (20.427 - 0.51259(VMC) + 0.02069(VMC)^2)(NOP)^{-0.16212} \qquad ..(7.14)$$

Alloy C2:

$$CR = (8.525 - 0.17197(VMC) + 0.00432(VMC)^2)(NOP)^{0.041145} \qquad ..(7.15)$$

Alloy C3:

$$CR = (18.653 - 0.90156(VMC) + 0.022076(VMC)^2)(NOP)^{0.22502} \qquad ..(7.16)$$

The values of the two factors constituting the models were computed and the data are summarized in the Table 7.7.

A scrutiny of the data summarized in the Table 7.7 revelaed that the corrosion rates predicted on the basis of the models agree well with the experimentally determined values. Secondly, the contribution of factor I to the corrosion rate follows a

systematic pattern, namely, with an increase in temperature/time of the heat treating its contribution reduces in all the three alloys and so also does the corrosion rate. Moreover its contribution to corrosion is inversely proportional to the Cu content(or the τ-stabilizing/carbide destabilizing tendency). This result is consistent with the analysis put forth in the earlier sections(sections 7.3-7.4) to explain the corrosion behaviour of the experimental alloys. However the contribution of the factor II did not appear to be consistent either in itself or with the corresponding variation in the NOP as influenced by temperature & time in the three experiential alloys(Table 7.7). A possible reason could be that the constants A1,A2,A3, and A4 have been calculated without exercising any constraint on the range over which they can vary. Alternatively, it was likely that the NOP is not a relevant representation of the effect of the dispersed second phase.

A single model(called the unified model) was also developed which could predict the corrosion behaviour of the three experimental alloys and is of the from:

$$CR = (18.653 - 0.53144(VMC) + 0.01497(VMC)^2)(NOP)^{0.04524} \qquad ..(7.17)$$

The predicted values of corrosion rate estimated on the basis of this model, were found to be in good agreement with the

experimentally determined values, barring few instances where considerable difference appeared (Table 7.8). However looking into the differences in the transformation behaviour of the experimental alloys elaborately discussed in Chapter-VI, the overall agreement between the predicted values of CR based on the 'unified model' and the experimentally determined values should be regarded as excellent.

3D-plots corresponding to the unified model (based on equation 7.17) is generating a surface in the form of an inverted parabola. Its operative profile over the admissible levels of VMC & NOP and the likely admissible levels of corrosion rates are shown in Figure 7.7. Although an impression is generated that lower corrosion rates could be attained, but practically this is not the situation since negative corrosion rates can not be attained.
The contour plot shown in the Figure 7.8 very usefully represent an interplay between NOP and VMC in controlling corrosion and the information summarized in it can be explained on a similar basis as the data contained in the Figures 7.7. An additional advantage of this figure is that it would be possible to predict corrosion rates for those heat treatments/conditions at which experimental data are not

available.

7.4.2.2 THE VMC-DF MODEL

Models(based on DF) Evaluated without constraints

Alloy C1:

$$CR = (13.388 - 0.38353(VMC) + 0.01394(VMC)^2)(DF)^{-0.15490} \qquad ..(7.18)$$

Alloy C2:

$$CR = (32.881 - 1.2331(VMC) + 0.03053(VMC)^2)(DF)^{-0.21524} \qquad ..(7.19)$$

Alloy C3:

$$CR = (22.692 - 1.0355(VMC) + 0.02842(VMC)^2)(DF)^{-0.07608} \qquad ..(7.20)$$

Models(based on DF) Evaluated with constraints

Alloy C1:

$$CR = (9.999 - 0.16190(VMC) + 0.00999(VMC)^2)(DF)^{-0.17935} \qquad ..(7.21)$$

Alloy C2:

$$CR = (9.999 + 0.13269(VMC) + 0.00304(VMC)^2)(DF)^{-0.05403} \qquad ..(7.22)$$

Alloy C3:

$$CR = (9.998 - 0.04625(VMC) + 0.00911(VMC)^2)(DF)^{-0.08734} \qquad ..(7.23)$$

Unified Model

$$CR = (16.066 - 0.36040(VMC) + 0.01274(VMC)^2)(DF)^{-0.05233} \qquad ..(7.24)$$

The data pertaining to the modelling of the corrosion behaviour based on the VMC-DF combination, as summarized in Tables 7.9-7.11 & Figures 7.9-7.12 can be explained on similar lines as the data pertaining to the VMC-NOP model. The

differences, if any, center around the figures depicting the data emerging from the unified model.

The profile of the resulting surface emerging from the unified model based on VMC-DF combination(Figure 7.12), although in itself planar, is essentially similar to the surface profile observed in the VMC-NOP unified model (Figure 7.7). It may be further mentioned that the overall data depicted in Figure 7.12 (in terms of attainable corrosion rates) is realistic in the sense that no negative corrosion rate values are envisaged. Thus, taking an overall view, the VMC-DF unified model provides a more realistic representation of the actual state of affairs when compared with the projections emerging from the VMC-NOP unified model.

Thus summing up, it is a happy augury that the explanation put forward to explain the corrosion behaviour of the alloys based on the VMC-NOP model is duly reflected in its behaviour based on the VMC-DF model namely the range over which DF varies having no effect in controlling the corrosion behaviour although the DF in itself does make a small yet uniform contribution. Further the role of the matrix and of a low Vf of MCs in controlling corrosion is more specifically highlighted. Thirdly, of the two 'unified models', the VMC-DF & VMC-NOP the former

combination appears to yield a more balanced picture of the relative effects of factors I and II in controlling corrosion as already discussed above. This appears reasonable since 'size distribution' as represented by DF is a more precise represen- tation of an assembly of particles rather than their actual number more so as the former also takes into consideration the number of particles.

7.4.3 INTERRELATION BETWEEN CORROSION AND DEFORMATION BEHAVIOUR

A perusal of the data on the corrosion and the deformation behaviour indicated that an 'improvement' in the deformation behaviour in general 'improved' corrosion resistance. It was therefore felt appropriate to establish such an interrelation. Mathematically it meant that

$$CS = A1 + A2 (X) \qquad \qquad \dots (7.25)$$

where X represents $\dfrac{CR}{CS}$. On calculating the constants as before, the models are

Alloy C1	$CS = 1892 + 25.43 (CR)$	...(7.26)
Alloy C2	$CS = 2475 - 1.79 (CR)$	...(7.27)
Alloy C3	$CS = 3768 - 84.02 (CR)$	...(7.28)

CS calculated on the basis of the above formulations are summarized in the Tables 7.12. Barring a few instances (wherein there was an error in estimating CS_{exp} due to defects in

specimens), there is an excellent agreement between the predicted and experimentally determined values of CS.

The above said formulations also reveal the possibility of estimating CR from CS values and if this is done, the agreement between the experimentally determined and predicted CR is very good.

7.5 CONCLUDING REMARKS

The data analyzed in sections 7.1-7.4 touches upon a number of new ideas, namely, assessment/modelling of the deformation behaviour, an analyses of the corrosion behaviour based on the weight loss studies to arrive at an overall 'performance' appraisal. The final sections deal with the modelling of the corrosion behaviour, efforts aimed at microstructural optimization with a view to assess the key parameter involved in corrosion control, checking on the 'physical consistency' of the models developed, plotting contour maps of CR vs VMC/NOP and CR vs VMC/DF not only to have a birds eye view but also with a view to finding out the corrosion behaviour under those conditions at which it has not been experimentally determined e.g. for 800°C and 850°C heat treatments.

GENERAL DISCUSSION, CONCLUSIONS, AND SUGGESTIONS FOR FUTURE WORK

8.1 GENERAL DISCUSSION

The present investigation has succeeded in assessing the transformation behaviour of the experimental alloys in a fair detail. The alloys intended to resist corrosion, were designed to include low cost indigenously available alloying elements Mn, Cr and Cu. Possible clues to their transformation behaviour were provided by their compositions and from previous work of Jain and Kumar [Jain (J2), Kuamr (K6)].

The alloys were so designed that austenite is retained in the as-cast condition itself thereby implying it to be the matrix. Optical metallography and x-ray diffractometry duly confirm this to be so. This is further confirmed through micro-hardness measurement which indicates the matrix hardness to be 350-360 VPN. However, in as-cast state and on heat treating from 800° and 850°C (independent of soaking period), microstructure comprises martensite. The reasons for it have already been explained at appropriate place. The black areas having differeing etching characteristics, identified as martensite, have a microhardness of 660 VPN. On heat treating from 900°C, the matrix is essentially austenitic and has microhardness ~ 400

VPN. The stability and volume fraction of austenite increased with an increase in the heat treating temperature/time but the same trend could not be related to copper content [i.e. while moving from alloy C1 (1.5% Cu) to C3 (5% Cu)]. It (stability of austenite) is, in general, accompanied by a simultaneous decrease in the volume fraction of massive carbides. This was corroborated through the EPMA, macrohardness and microhardness measurements; e.g. the microhardness of the matrix increased from 400 VPN as above to 420 VPN obtained on heat treating at 1000°C, thereby confirming increased stability of the matrix due to increased solute enrichment. X-ray diffractometric studies confirmed this through a decrease in the diffraction angle. The above changes, brought about by increasing the heat treating temperature/soaking period, were conducive to improving the corrosion resistance (which showed improvement with increased copper content) and the deformation behaviour.

The second phase in the as-cast microstructure is massive carbide only. Three types of massive carbides were observed, namely, massive/platy type, eutectic type, and mesh type. Massive carbides have a hardness of 650-700 VPN and flower type carbides 1000-1100 VPN. On heat treating, the following changes have been observed:

1. Mesh type carbide disappeared(dissolved) and dispersed second phase precipitated from the austenitic matrix.

2. There was a considerable variation in the chemical composition of the carbides as ascertained through EPMA and corroborated by micro-hardness measurements. As already discussed, the Vf of MCs decreased with an increase in the heat treating temperature/time and the 'rounding off' tendency was observed at 950/1000°C heat treatments. On heat treating from higher temperatures massive carbides assumed different morphologies such as rounded, hexagonal etc. So also it appeared that there was an increase in the Vf of discontinuous free carbides, some of which appeared to form though agglomeration of DCs.

Massive/platy carbides have a micro-hardness of 800 VPN at 800°C, 1000 VPN at 1000°C, and 1120 VPN at 1050°C whereas the free carbides have micro-hardness of 1100 VPN at 800°C, 1500-1600 VPN at 1000°C, and 1600-1800 VPN at 1050°C heat treatments.

At 1050°C, 6 & 10 hours heat treatment, a 'peculiar' feature involving 'agglomeration' of massive carbides was observed. These carbides have micro-hardness of 1800 VPN and the dark phase in between the agglomerating carbides has a micro-hardness of 850 VPN. EPMA studies revealed that the dark grey

regions in between the agglomerating MCs would become MCs except for their Cu and Si content.

3. Optical metallography and EPMA studies have revealed two types of massive carbides on heat treating at 900/950°C differing in their Cr content by about 10%. The inherent nature of the white cast irons to form heterogeneous structures may have lead to such an occurrence. This could be one of the reasons for deterioration in the corrosion resistance and deformation behaviour on heat treating from these temperatures.

As already discussed, dispersed second phase(DSP) precipitated from the austenitic matrix on heat treating from 800°C and 850°C. They essentially comprised needles(plates) + DCs up to 900°C, 10 hours heat treatments, only DCs up to 950°C, 10 hours heat treatments, and reprecipitated particles of Class I size upon heat treating up to 1050°C, 6 hours. DCs finally dissolved on raising the temperature/time. The dispersed second phase adversely influences corrosion behaviour due to an unfavorable morphology and enhanced galvanic action. However, it is the heterogeneity of the matrix which appears to have a more dominant effect on the corrosion behaviour than the dispersed second phase. The DSPs and MCs have more pronounced effect on the deformation behaviour. Deformation behaviour was assessed on the

basis of compression testing. In some of the instances the experimentally determined values have been low due to defects in specimen present in the form of a pipe running right through the casting.

Optical metallography revealed a similarity between the needle type DSPs and DCs. X-ray diffractometric studies have shown them to be M_5C_2/M_3C whereas EPMA indicated them to be M_3C/M_7C_3 type carbide. Not much is known as to whether M_5C_2 could form in the experimental alloys. The possibility that these needles are partly M_3C and/or partly M_7C_3/M_5C_2 type carbides can not be ruled out.

EPMA studies also revealed the possibility of the formation of extraneous phases besides providing the useful data on the partitioning behaviour of Mn, Cr and also Cu.

Extensive 'modelling work' has provided a wealth of the information on the transformation behaviour, 'second phase' characteristics, and the 'overall performance' which has major 'fundamental and applied implications'.

8.2 CONCLUSIONS

Under the experimental conditions, the following conclusions are arrived at:

1. Corrosion resistant cast irons can be developed through 'white iron' route employing low cost indigenously available alloying

on selecting the hardness values at two extremities of heat treating periods(2 hours & 10 hours) at 800 & 1050°C and at an additionally selected heat treating temperature(900°C). The simulated models are-

C1 : H = 204.5 $e^{1051/T}$ + (0.01144-0.1111x10^{-4}T)t

Overall SD = 14.844

C2 : H = 222.4 $e^{1013/T}$ + (0.00872-0.9167x10^{-5}T)t

Overall SD = 6.752

C3 : H = 204.5 $e^{1051.1/T}$ + (0.01144-0.1111x10^{-4}T)t

Overall SD = 4.955

Thus the transformation behaviour can be simulated with reasonably high accuracy on the basis of only six data points as against the original thirty.

12. 3-D plots interrelating temperature and time with hardness revealed that the 'change over' at which the second factor in the above model becomes negative can be represented by a surface. Iso-hardness plots for the experimental alloys revelaed the range over which hardness varied and the different temperature and time combinations to arrive at a desired hardness.

13. A new parameter 'distributional homogeneity/heterogeneity' of the microstructure has been defined.

(i) The overall homogeneity/heterogeneity(based on Vf of

basis of compression testing. In some of the instances the experimentally determined values have been low due to defects in specimen present in the form of a pipe running right through the casting.

Optical metallography revealed a similarity between the needle type DSPs and DCs. X-ray diffractometric studies have shown them to be M_5C_2/M_3C whereas EPMA indicated them to be M_3C/M_7C_3 type carbide. Not much is known as to whether M_5C_2 could form in the experimental alloys. The possibility that these needles are partly M_3C and/or partly M_7C_3/M_5C_2 type carbides can not be ruled out.

EPMA studies also revealed the possibility of the formation of extraneous phases besides providing the useful data on the partitioning behaviour of Mn, Cr and also Cu.

Extensive 'modelling work' has provided a wealth of the information on the transformation behaviour, 'second phase' characteristics, and the 'overall performance' which has major 'fundamental and applied implications'.

8.2 CONCLUSIONS

Under the experimental conditions, the following conclusions are arrived at:

1. Corrosion resistant cast irons can be developed through 'white iron' route employing low cost indigenously available alloying

elements Mn,Cr, and Cu. The microstructures that were characterized for their deformation and corrosion behaviour(in 5% NaCl solution) are A + MC + DSPs, A + MC + DC, A + MC, A + MC(agglomerated). All these microstructures were generated through heat treatments. The temperature ranges over which the different microstructures exist are given below:

As-cast	: A + M + MC
up to 850°C	: A + M + DCs
up to 950°C	: A + MC + DCs
up to 1050°C	: A + MC

2. The volume fraction of MC decreased with temperature or with soaking period at a given heat treating temperature. The decrease was marked at temperatures ≥ 950°C. MCs were rendered discontinuous on heat treating from 900/950°C. The 'rounding off' tendency(in MCs) set in at 950°C; and an increase in Cu content accelerated this process. Agglomeration amongst MCs was observed at 1050°C. This has perhaps stalled the expected marked decrease in the Vf of MCs at 1050°C, 10 hours heat treatment.

3. Dispersed second phase formed on heat treating at ≥ 800°C comprised (a) needles + dispersed carbides up to 950°C, 10 heat treatment, only dispersed carbides upto 1000°C, 10 hours heat treatment, (b) then dissolved into matrix, and (c) again

reappeared at 1050°C, 2 hours heat treatment as class-I particles. The DSP forms by a mechanism involving precipitation from austenite and also during air cooling. Particles constituting them belonged to Classes I and II(size up to 1.16 microns). As the heat treating temperature/soaking duration is raised the overall spread of the particles is increased to Class IV (size up to 3.32 microns).

4. Dispersed carbides underwent coarsening which was characterized by the 'spill over' of the particles into classes III and IV. Coarsening was assessed with the help of coarsening index.

5. DCs get dissolved at 1000°C heat treatment and reappeared on heat treating at 1050°C, 2 hours as Class I size particles and again dissolved at 1050°C 6 hours heat treatment.

6. The carbides to form in the experimental alloys are M_3C, M_7C_3, and M_5C_2. The massive carbides are mostly of the type M_3C/M_7C_3. The haloed regions observed are essentially massive carbides but with 10% less Cr. The dark grey regions between 'agglomerating massive carbides' approxi- mately exhibit the same composition as the agglomerating MCs except for their Cu and Si content. The dispersed carbides and needles are M_3C/M_5C_2 type. The carbide transformation sequence is:

Carbide	Stability range
M_3C + M_5C_2 + M_7C_3	As-cast state in all the investigated allys.

|

| M_3C + M_5C_2 + M_7C_3 | up to 850°C (M_3C present in traces in C3) |

|

| M_5C_2 + M_7C_3 | up to 1000°C in C1 & C3
up to 1050°C in C2 |

|

| M_5C_2 + M_7C_3
+ M_3C(reforming) | up to 1000°C in C2 & C3
up to 1050°C in C1 |

|

| M_5C_2 (some/traces) + M_7C_3 | up to 1050°C |

|

| M_3C + M_5C_2(?)
+ M_7C_3 (some amount) | up to 1050°C; higher SP |

|

Predominant carbides at high temperature are M_7C_3 & M_5C_2 (small/traces)

7. Hardness in general decreased with an increase in the heat treating temperature in the order :

   H_{1050} < H_{1000} < H_{950} < H_{900} < H_{850} < H_{800}

8. For a given heat treating temperature, hardness varied linearly with the soaking period. There is a general decrease in hardness with increase in soaking period for all

the alloys. However, the effect is more marked at higher heat treating temperatures ($\geq$ 950°C). The increase/decrease exhibited by the alloys with increase in soaking period at low temperatures say 800° and 850°C is very marginal for a given heat treating temperature.

9. For a given heat treating period, the variation in hardness with temperature was in the form of inverted parabola.

10. Transformation behaviour of the alloys, over the entire range of temperature and soaking period, on being modelled is of the form:

C1 : $H = 271.701\ e^{838.513/T} + (0.005809 - 0.547 \times 10^{-5}T)t$

Overall SD = 1.593

C2 : $H = 342.517\ e^{551.093/T} + (0.01688 - 0.158 \times 10^{-4}T)t$

Overall SD = 4.524

C3 : $H = 287.256\ e^{692.334/T} + (0.01777 - 0.163 \times 10^{-4}T)t$

Overall SD = 3.053

Where T = temperature in °K

t = time in seconds

H = hardness, HV_{30}

The first parameter models the matrix transformation and the second parameter the carbide transformation

11. The aforesaid transformation behaviour of the experimental alloys can be 'simulated' through mathematical modelling based

269

on selecting the hardness values at two extremities of heat treating periods(2 hours & 10 hours) at 800 & 1050°C and at an additionally selected heat treating temperature(900°C). The simulated models are-

C1 : H = 204.5 $e^{1051/T}$ + (0.01144-0.1111x10⁻⁴T)t

Overall SD = 14.844

C2 : H = 222.4 $e^{1013/T}$ + (0.00872-0.9167x10⁻⁵T)t

Overall SD = 6.752

C3 : H = 204.5 $e^{1051.1/T}$ + (0.01144-0.1111x10⁻⁴T)t

Overall SD = 4.955

Thus the transformation behaviour can be simulated with reasonably high accuracy on the basis of only six data points as against the original thirty.

12. 3-D plots interrelating temperature and time with hardness revealed that the 'change over' at which the second factor in the above model becomes negative can be represented by a surface. Iso-hardness plots for the experimental alloys revelaed the range over which hardness varied and the different temperature and time combinations to arrive at a desired hardness.

13. A new parameter 'distributional homogeneity/heterogeneity' of the microstructure has been defined.

(i) The overall homogeneity/heterogeneity(based on Vf of

MCs) of an alloy as influenced by heat treating parameters has been defined as

$$H_M = \frac{\text{The net variation in Vf of MCs around a mean}}{\text{Permissible variation around a mean}}$$

or

$$= \frac{SD_{exp}}{SD_{per}} \times \frac{[Vf_{max,per} - Vf_{min,per}]}{[Vf_{max,exp} - Vf_{min,exp}]}$$

This could be expressed as a fraction or percent. Under ideal condition $H_M = 1$. Homogeneity can be assessed depending upon the permissible variation in the parameter(s) being measured.

Heterogeneity = 1 - Homogeneity

(ii) Distributional heterogeneity, H_M(dist) (related with precipitated second phase) has been expressed as

$$= \frac{\text{Deviation in distribution function/factor with respect to the majority size fraction}}{\text{Overall distribution function/factor}}$$

or more precisely

$$H_M(dist) = \frac{\text{underspill ratio X spillover ratio}}{\text{overall distribution factor}}$$

expressed as a ratio or as percentage.

14. The dispersed second phase has been represented by a parameter called the 'distribution factor' which is given by the expression

271

$$DF = \frac{\sum\limits_{i=1}^{n} X_i . N_i}{\sum\limits_{i=1}^{n} N_i}$$

where, n = the number of classes,

N_i = the number of particles in i^{th} class,

X_i = volume fraction in the ith class /VDC,

and, VDC = total volume fraction of dispersed carbides.

15. X-ray diffractometric studies proved helpful in establishing the presence of 'martensite islands' in the as-cast structure and in deciding upon the likely identity of the MCs and the DSPs.

16. EPMA confirmed that the carbides to form mostly comprised M_3C and M_7C_3, the needle like DSPs are in fact carbides, that on heat treating at 900/950°C two types of carbides differing in their Cr content by about 10% formed and that the dark etching regions abridging agglomerating carbides in fact have a composition close to M_7C_3 except for their Cu and Si content. In addition to the above, useful partitioning data on the distribution of Mn and Cr into the matrix and carbide phases has been generated.

17. DTA data showed that whereas the alloys C1, C2, and C3 undergo the (i) martensite —> austenite as well as internal

oxidation reaction at 540-575°C, and (ii) carbide transformation(s) involving a transition of M_3C to M_7C_3 via M_5C_2 transition carbide at 960-980°C, an additional transformation occurred in C1 and C2 at 740-760°C.

18. TG data showed that the as-cast microstructure was suitable up to 600°C.

19. Mathematical modelling of the TG data showed that %TG is related to the temperature by the equation

Alloy C1 $\%TG = 2.2761 + 7999.65 \exp(-7929.25/T)$

Alloy C2 $\%TG = 2.5190 + 7426.91 \exp(-7999.98/T)$

Alloy C3 $\%TG = 1.9690 + 6046.54 \exp(-7999.98/T)$

20. The deformation studies carried out on the experimental alloys have established that compressive strength improved on heat treating. CS is not linearly interrelated with hardness as is found in the case of steels. It is because of the heterogeneous nature of the microstructure generally found in cast irons. It was established that the CS can be related with hardness through a second order polynomial.

Alloy C1 : $R = -11.58 + 0.0667H - (0.6926E-04) H^2$

Alloy C2 : $R = 36.92 - 0.1299H + (0.1227E-03)H^2$

Alloy C3 : $R = 24.98 - 0.0629H + (0.4249E-04)H^2$

where $R = CS/H$,

H = hardness, HV_{30},

21. From the point of view of mechanical properties, austenite based microstructure with little dispersed second phase and containing 'appropriate' volume fraction of 'massive second phase' with near 'rounded' morphology are the most suitable. Accordingly high CS is obtained on heat treating from high temperatures (1050°C). The effect of DCs on the deformation behaviour depends upon their size, shape, and distribution. Similarly the effect of MC is governed by their volume fraction, morphology, and compatibility with the matrix.

22. Corrosion rate in the as-cast condition is consistent with its microstructure. It, in general, decreased with an increase in the heat treating temperature/soaking duration and also with an increase in Cu content(i.e. while moving from alloy C1 to C3) due to enhanced stability and a larger volume fraction of austenite and simultaneous decrease in the Vf of MCs; the exceptions are those heat treatments which produced adverse microstructural feature namely matrix heterogeneity, and aligned DCs.

23. The effect of dispersed second phase on corrosion resistance depends on their size, shape and distribution. In the present study dispersed particles affected the corrosion resistance adversely to some extent as is seen on heat treating from 900 and 950°C. Heat treatment 1050°C, 10 hour, AC provided the

best corrosion resistance and most useful deformation behaviour.

24. Corrosion rate is interrelated with the volume fraction of VCb (MC + DC) and NOP through the following equations

Alloy C1: $CR = (19.982 - 0.37157(VCb) + 0.02125(VCb)^2)(NOP)^{-0.26838}$

Alloy C2: $CR = (12.316 - 0.26605(VCb) + 0.00652(VCb)^2)(NOP)^{0.22482}$

Alloy C3: $CR = (13.354 - 0.45377(VCb) + 0.01147(VCb)^2)(NOP)^{0.23459}$

where CR = corrosion rate in mdd

VCb = total volume fraction of MCs + DCs

NOP = number of particles(DSPs)

This model when modified as

$CR = (C1 + C2 (VMC) + C3 (VMC)^2)(NOP)^{C4}$

gave a more representative idea of the true physical happenings

Alloy C1:

$CR = (20.427 - 0.51259(VMC) + 0.02069(VMC)^2)(NOP)^{-0.16212}$

Alloy C2:

$CR = (8.525 - 0.17197(VMC) + 0.00432(VMC)^2)(NOP)^{0.041145}$

Alloy C3:

$CR = (18.653 - 0.90156(VMC) + 0.02207(VMC)^2)(NOP)^{0.22502}$

25. On incorporating the effect of DC on the basis of the distributional factor(DF), the above equations are modified as:

Alloy C1: CR = $(13.388-0.38353(VMC)+0.01394(VMC)^2)(DF)^{-0.15490}$

Alloy C2: CR = $(32.881-1.2334(VMC)+0.03053(VMC)^2)(DF)^{-0.21524}$

Alloy C3: CR = $(22.692-1.0355(VMC)+0.02842(VMC)^2)(DF)^{-0.07608}$

and again when constraints are imposed on the constants of the equation while optimizing, the equations so obtained are-

Alloy C1:

CR = $(9.999-0.16190(VMC)+0.00999(VMC)^2)(DF)^{-0.17535}$

Alloy C2:

CR = $(9.999+0.13269(VMC)+0.00304(VMC)^2)(DF)^{-0.05403}$

Alloy C3:

CR = $(9.998-0.04625(VMC)+0.00911(VMC)^2)(DF)^{-0.08734}$

and 'truly' represented the effect of second phase on the corrosion resistance.

26. A 'unified model' describing the corrosion behaviour of all the experimental alloys has been obtained and is of the form

(i) CR vs VMC & NOP

CR = $(18.653-0.53144(VMC)+0.01497(VMC)^2)(NOP)^{0.04524}$

(ii) CR vs VMC & DF

CR = $(16.066-0.36040(VMC)+0.01274(VMC)^2)(DF)^{-0.05233}$

The aforesaid models especially the latter predict the corrosion behaviour of the alloys with excellent accuracy.

27. On the basis of specially constructed contour plots, it is possible to predict the corrosion behaviour for those heat

treatments at which experimental assessment of the corrosion rates has not been carried out. An equally important aspect is that from the 3-D and contour plots it is possible to determine the 'performance controlling features' for the experimental alloys, e.g. in the present study corrosion essentially centers around reducing the volume fraction of MCs and matrix heterogeneity seemed to have a larger adverse effect than the adverse effect associated with unfavorable morphology of the DSPs. For controlling the deformation behaviour, a careful control over the distribution of massive and second phase particles is more specifically required.

28. From the 'overall performance' point of view alloy C2 (C3) has been found to be better than C1 and C3 (C2). Hence it is recommended that the future modifications in the alloy chemistry should incorporate the beneficial features of the composition C2 (C3) which have many positive features. Further, the alloying elements should be so adjusted that the microstructures of interest(formed in the present investigation at 1000 and 1050°C) should form in the as-cast condition or on heat treating at lower temperatures i.e. say up to 800°C heat treatment.

29. The above said discussion reveals that a detailed study of the phase transformations and of the resulting microstru- ctures

has major technological fallout and major implications in the design of future alloy compositions to obtain the best corrosion resistance and deformation behaviour.

8.3 SUGGESTIONS FOR FUTURE WORK

The future work should be carried out on the following lines:

1. Detailed study of the nature and formation of needles at lower heat treating temperature and dark grey phase at high temperature heat treatments.

2. Further work on the defining the 'homogeneity/heterogeneity' index of the microstructure.

3. Extensive electro-chemical characterization of different microstructures by potentiostatic methods.

4. Crystal structure determination of carbides by x-ray diffractometry.

5. Detailed study of the high temperature behaviour of the alloys in the heat treated condition.

6. Studying the founding characteristics of the alloys

7. Detailed investigations of the performance of the experimental alloy C2.

TABLE 1.1

CONDITIONS FAVOURING EACH OF THE EUTECTIC REACTIONS IN CAST IRONS

A. Formation of grey iron, ductile iron, compacted graphite iron

    1. High Carbon Equivalent

    2. High Silicon

    3. Presence of Graphitizers eg. Cu, Ni

    4. Slow Cooling

    5. Thick Casting

    6. Inoculation

B. Formation of white iron

    1. Low Carbon Equivalent

    2. Low Silicon

    3. Presence of Carbide Formers eg. Cr, Mo, V

    4. Fast Cooling

    5. Thin Castings

    6. No Inoculation

TABLE 1.2

MECHANICAL AND PHYSICAL PROPERTIES OF C.G. IRONS

Property	Microstructure	
	Ferrite	Pearlite
Tensile strength N/mm^2	310	420
Yield strength N/mm^2	270	345
Elongation %	4	2
Hardness	150	200
C.V.N. impact, J	5	3
Fatigue strength (N/mm^2)	150	180
Elastic modulus GN/m^2	165	165
Poissons ratio	0.265	0.265
Thermal conductivity W/(mK)	44	36
Specific heat at 100°C, J/g^{o}C	0.5	0.5
Coefficient of linear thermal expansion, X10^{-6}/^{o}C	11	13

TABLE 1.3

MECHANICAL AND PHYSICAL PROPERTIES OF COMPACTED GRAPHITE, GREY AND NODULAR IRONS

Property	Grey irons	CG irons	SG irons
Tensile strength N/mm^2	160-320	300-600	400-700
Ton/in^2	11-20	20-38	26-45
Elongation %	Nil	3-6	6-25
Modulus of elasticity lb/in^2	14-16x10^{-6}	20-23x10^{-6}	25-27x10^{-6}
Charpy impact (J) at room temperature	Nil	3-7	17
Thermal conductivity Cal/cm ^{o}C/sec	0.11-0.14	0.10-0.12	0.08-0.09
Damping capacity	13.2x10^{-4}	4-6x10^{-4}	2-5x10^{-4}
Fatigue limit un-notched ton/in^2	7-8	15-20	12-18
Machineability	Very good	Very good	Good
Corrosion Resistance	Moderate	Intermediate	Good

TABLE-1.4a

RANGES OF ALLOY CONTENT FOR THE CORROSION & HEAT RESISTANT ALLOYED GREY CAST IRONS

Description	TC(a)	Mn	P	S	Si	Ni	Cr	Mo	Cu	Matrix structure as-cast(c)
COMPOSITION, (Wt %) (b)										
Corrosion-Resistant Irons										
High silicon iron(d)	0.4-1.1	1.5	0.15	0.15	14-17	...	5.0	1.0	0.5	F
Ni-Cr grey iron(e)	3.0	0.5-1.5	0.08	0.12	1.0-2.8	13.5-36	1.5-6.0	1.0	7.0	A
Ni-Cr ductile iron(f)	3.0	0.7-4.5	0.08	0.12	1.0-3.0	18-36	1.5-5.5	1.0	...	A
Heat-Resistant Grey Irons										
Medium silicon iron(g)	1.6-2.5	0.4-0.8	0.30	0.10	4.0-7.0	...	...	...	...	F
High Cr-iron	1.2-4.0	0.3-1.5	0.15	0.15	0.5-3.0	5.0	12-35	4.0	3.0	F,CP
Ni-Cr iron(e)	1.8-3.0	0.4-1.5	0.15	0.15	1.0-2.7	13.5-36	1.8-6.0	1.0	7.0	A
Ni-Cr-Si iron(h)	1.8-2.6	0.4-1.0	0.10	0.10	5.0-6.0	13-43	1.8-5.5	1.0	...	A
Heat-Resistant Ductile Irons										
High Al-iron	1.3-2.0	0.4-1.0	0.15	0.15	1.3-6.0	...	20-25 Al	...	...	F
Medium Si-ductile iron	2.8-3.8	0.2-0.6	0.08	0.12	2.5-6.0	1.5	...	...	...	F
Ni-Cr ductile iron(f)	3.0	0.7-2.4	0.08	0.12	1.75-5.5	18-36	1.75-3.5	1.0	...	A

(a) Where a single value is given rather than a range, that value is a maximum limit
(b) Total Carbon
(c) F, Ferrite; A, austenite; CP, coarse pearlite
(d) such as Duriron, Durichlor 51, Superchlor
(e) Such as Ni-Resist austenitic iron (ASTM A436)
(f) Such as Ni-Resist austenitic ductile iron (ASTM A439)
(g) Such as Silal   (h) Such as Nicrosilal

TABLE-1.4b

TYPICAL MECHANICAL PROPERTIES OF CORROSION RESISTANT CAST IRONS

Type of iron	Hardness, HB	Tensile strength		Compressive strength		Impact energy		Transverse breaking load(b)		Transverse deflection(b)	
		MPa	ksi	MPa	ksi	J	ft·lb	kg	lb	mm	in.
High-silicon iron	480 to 520	90 to 180	13 to 26	690	100	2.7 to 5.4	2 to 4(c)	545 to 1000	1200 to 2200	0.65	0.026
High-chromium iron	250 to 740	205 to 830	30 to 120	690	100	0.1 to 3(d) 27 to 47(c)	0.1 to 2(d) 20 to 35(c)	910 to 1590	2000 to 3500	1.5 to 3.8	0.06 to 0.15
High-nickel gray iron	120 to 250	170 to 310	25 to 45	690 to 1100	100 to 160	80 to 200(c)	60 to 150(c)	820 to 1590	1800 to 3500	5 to 25	0.20 to 1.00
High-nickel ductile iron	130 to 240	380 to 480	55 to 70	1240 to 1380	180 to 200	14 to 40(d)	10 to 30(d)	...	...	...	...

(b) For as-cast 30.5-mm (1.2-in.) diam bar broken over a 457-mm (18-in.) span. (c) Unnotched 30.5-mm diam test bar broken over a 152-mm (6-in.) span in a Charpy testing machine. (d) Standard Charpy.

TYPICAL MECHANICAL PROPERTIES OF HEAT RESISTANT ALLOY CAST IRONS

Type of iron	Hardness, HB	Tensile strength		Compressive strength		Impact energy		Transverse breaking load(b)		Transverse deflection(b)	
		MPa	ksi	MPa	ksi	J	ft·lb	kg	lb	mm	in.
Medium-silicon gray iron	170 to 250	170 to 310	25 to 45	620 to 1040	90 to 150	20 to 31(c)	15 to 23(c)	455 to 1090	1000 to 2400	4.6 to 8.9	0.18 to 0.35
High-chromium gray iron	250 to 500	210 to 620	30 to 90	690	100	27 to 47(c)	20 to 35(c)	910 to 1590	2000 to 3500	1.5 to 3.8	0.06 to 0.15
High-nickel gray iron	130 to 250	170 to 310	25 to 45	690 to 1100	100 to 160	80 to 200(c)	60 to 150(c)	820 to 1360	1800 to 3000	5 to 25	0.2 to 1.0
Ni-Cr-Si gray iron	110 to 210	140 to 310	20 to 45	480 to 690	70 to 100	110 to 200(c)	80 to 150(c)	820 to 1130	1800 to 2500	7 to 35	0.3 to 1.4
High-aluminum gray iron	180 to 350	235 to 620	34 to 90	...	...	...	...	...	...	...	...
Medium-silicon ductile iron	140 to 300	415 to 690	60 to 100(c)	...	...	7 to 155(d)	5 to 115(d)	...	...	...	...
High-nickel ductile iron (20 Ni)	140 to 200	380 to 415	55 to 60(e)	1240 to 1380	180 to 200	16(f)	12(f)	...	...	...	...
High-nickel ductile iron (23 Ni)	130 to 170	400 to 450	58 to 65(g)	...	...	38(f)	28(f)	...	...	...	...

(b) Unnotched 30.5-mm (1.2-in.) diam test bar broken on 152-mm (6-in.) diam supports in a Charpy testing machine. (c) Yield strength. 310 to 520 MPa (45 to 75 ksi); elongation, 0.2%. (d) Standard Charpy test on 10-mm unnotched specimen. (e) Yield strength. 210 to 240 MPa (30 to 35 ksi); elongation, 8 to 20%. (f) Standard Charpy test on 10-mm notched specimen. (g) Yield strength. 195 to 240 MPa (28 to 35 ksi); elongation, 20 to 40%.

TABLE-1.5a

CHEMICAL COMPOSITION OF Ni-RESIST IRONS, PERCENT

	Type 1[1] Aus 101a	Type 1B Aus 101b	Type 2[2] Aus 102a	Type 2B Aus 102b	Type 3 Aus 105	Type 4	Type 5
C	3.00 max	3.00 max	3.00 max	3.00 max	2.60 max	2.60 max	2.40 max
Si	1.00-2.80	1.00-2.80	1.00-2.80	1.00-2.80	1.00-2.00	5.00-6.00	1.00-2.00
Mn	1.00-1.50	1.00-1.50	0.80-1.50	0.80-1.50	0.40-0.80	0.40-0.80	0.40-0.80
Ni	13.50-17.50	13.50-17.50	18.00-22.00	18.00-22.00	28.00-32.00	29.00-32.00	34.00-36.00
Cu	5.50-7.50	5.50-7.50	0.50 max	0.50 max	0.50 max	0.50 max	0.50 max
Cr	1.75-2.50	2.75-3.50	1.75-2.50	3.00-6.00[3]	2.50-3.50	4.50-5.50	0.10 max[4]

1 Where the presence of copper offers corrosion-resistance advantages, Type 1 is recommended.

2 For handling caustics, food, etc., where copper contamination cannot be tolerated, Type 2 is recommended.

3 Where some machining is required; the 3 0-4.0 chromium level is recommended.

4 Where higher hardness, greater strength and added heat resistance are desired, the chromium may be 2.5-3.0% at the expense of increased expansivity.

TABLE-1.5b

MECHANICAL PROPERTIES OF Ni-RESIST IRONS

	Type 1 Aus 101a	Type 1B Aus 101b	Type 2 Aus 102a	Type 2B Aus 102b	Type 3 Aus 105	Type 4	Type 5

TABLE-1.7

COMMERCIAL APPLICATIONS FOR NI-RESIST DUCTILE IRONS

INDUSTRY	APPLICATIONS	REASONS FOR USE	INDUSTRY	APPLICATIONS	REASONS FOR USE
Chemical Process	pumps, valves	corrosion resistance heat resistance	Liquid Handling (Cont.)	valves body, bushing, butterfly gates, glands, pistons, piston rings	for high temperature service up to 1400 F
	supports and frames	corrosion resistance			
	kettles	corrosion resistance erosion resistance wear resistance	Petroleum	pumps, valves	corrosion resistance
				tube supports	heat resistance high temperature strength
	filters	corrosion resistance erosion resistance wear resistance		furnace castings	heat resistance
Electrical	nonmagnetic housings	low magnetic permeability	Power (Steam)	pumps, valves	corrosion resistance heat resistance
	switchgear	low magnetic permeability machinability		turbine diaphragms	corrosion resistance steam erosion resistance wear resistance
	pole line hardware	low magnetic permeability corrosion resistance		control valves	corrosion resistance steam erosion resistance wear resistance selected expansion
Internal Combustion Engines	ring bands and hot spot buttons for aluminum pistons	heat resistance high temperature strength wear resistance erosion resistance high expansion machinability		shaft seals	erosion resistance wear resistance
				pipe and fittings	corrosion resistance erosion resistance
	exhaust manifolds, turbocharger cases and diffusers	heat resistance erosion resistance wear resistance high temperature strength selected expansion	Pulp and Paper	pumps, valves	refer to liquid handling field
				sweat rolls	corrosion resistance
				cowan screen frames	high strength corrosion resistance
	valve guides	heat resistance wear resistance corrosion resistance erosion resistance selected expansion	General	supports and frames	corrosion resistance
				furnace castings	heat resistance
				glass molds	high temperature strength heat and scale resistance selected expansion
	cylinder liners	corrosion resistance wear resistance erosion resistance high strength		winch drums and brakes	corrosion resistance high strength nonmagnetic properties wear resistance
	water pump bodies and impellers	corrision resistance erosion resistance wear resistance		sewage plant castings	erosion resistance corrosion resistance wear resistance
	turbine cases	heat resistance high temperature properties selected expansion		water works, valves, flood gates	corrosion resistance erosion resistance
Liquid Handling	pumps—stationary parts	corrosion resistance		dishwasher pumps and manifolds	corrosion resistance erosion resistance high temperature strength
	cases or bodies	graphitic corrosion resistance			
	end plates	wear		textile rolls	heat resistance
	wear rings	wear resistance		hot forming dies	heat resistance high temperature strength wear resistance
	cylinder liners	machinability			
	diaphragms	high strength			
	pumps—moving parts impellers	cavitation erosion resistance		glass rolls	minimum coefficient of thermal expansion heat resistance high temperature strength
	shaft sleeves	galvanic corrosion resistance			
	pistons seals, valves, gears	for high temperature service up to 1400 F		sintering machine pallets	heat oxidation resistance high temperature strength
	fittings, meters, pipe	same reasons apply as for pumps			

TABLE-2.1

COMPOSITION AND PROPERTIES OF SOME REPRESENTATIVE PLAIN CARBON WHITE IRONS

Sl. No.	Type/Class Designation	COMPOSITION					Hardness BHN	Micro-structure	Wear Rate (relative)	Application
		TC	Si	Mn	S	P				
1.	Pearlitic Iron	2.80	0.3	0.4	0.15	0.1-0.12	415-477	C+P	179.0	Grinding Balls
2.	Unalloyed, low hardness Iron	3.0	0.75	0.25	0.4	0.12	320-440	C+P	—	Iron Rolls
3.	Unalloyed high hardness Iron	3.5	0.5	0.25	0.4	0.12	440-520	C+P	—	Iron Rolls

*Wear rates are relative to an assigned rate of 100 for Chil' Cast Unalloyed Iron

PHYSICAL AND MECHANICAL PROPERTIES

1. Hardness (DPN)
   410 520 (sand Cast)
   435-550 (Chill Cast) (abrasion resistant)
   400 (L.C., 2.5-2.6%C)
   650 (H.C., 3.75-4.0%C)

2. Tensile strength (ton/in²)
   15-30 (sand Cast)
   18-30 (Chill Cast)
   16-18 (H.C., 3.0—3.5%C) (Pearlitic, Hard)
   18-30 (L.C., 2.75—2.9%C) (Pearlitic, Tough)
   30 (Sand Cast, Chill Cast)

3. Modulus of elasticity (lb/in² x10⁶)

4. Transverse rupture stress 1.2 bar, 12 in span (ton/in²)
   24-40 (Sand Cast)
   33-47 (Chill Cast)

5. Transverse deflection
   0.05-0.1 (H.C., 3.0—3.5%C)
   0.07-0.11 (L.C., 2.75 — 2.9%C)

6. Specific gravity
   7.6—7.8

7. Electrical resistivity (microhm:cm³ at 78°F)
   55—72

8. Impact strength (0.798 in dia machined from 0.875 in as-cast dia.) (ft. lb.)
   6-11 (impact strength of white cast iron is about one third that of gray iron)

9. Thermal conductivity (Cal|cm³|s|°C)
   0.035—0.076

10. Thermal expansion coefficient 0-276°C 276-684°C
    $10\text{-}11 \times 10^{-6}$
    $15.9\text{-}16.4 \times 10^{-6}$

11. Yield strength
    Usually not determined because of low ductility of white irons. The yield strength is considered to be close to the tensile strength.

TABLE-3.1

Summary of the structure-property relations in some Fe-Mn-Cr-Cu corrosion resistant cast irons

(1) Alloys studied	3%C, 5%Cr, 6.8%Mn, 1.5-3.0%Cu cast irons
(2) Heat treatments	Held at 800,850,900,950,1000 and 1050°C for 2,4,6,8, and 10 hours followed by OQ(62) and AC(83).
(3) Microstructures	(a) As-Cast: P/B + M + MC + some RA (b) Upto 900°C: M + τ + MC + DC (c) Upto 1000°C: τ + DC + MC or τ + MC (d) At 1050°C: τ + MC (M_7C_3 in eutectic form)
(4) Effect of cooling	OQ: larger τ, lesser DC AC: more DC, lesser τ, 'M' up to higher heat treating temperatures
(5) various carbides formed	M_3C, M_5C_2, M_7C_3, and $M_{23}C_6$ M_3C: up to 950°C prolonged soaking $M_{23}C_6$: boundary carbide up to 900°C,10 hrs. M_5C_2 & M_7C_3: up to 1050°C

(6) Structure-Property interrelations

    (a) Martensite : Resists corrosion, but embrittles

    (b) Austenite : Most desirable matrix to resist corrosion & to give good strength and ductility. Increase in the amount and stability enhance properties.

    (c) Dispersed Carbides:

            -They precipitate as M_3C/M_5C_2 from matrix during heat treatment (represented as no. of particles or by distribution factor).
            -Overall adverse effect on properties;attains a maximum at 950°C, 10 hours treatment

    (d) Massive carbides:

            -Represented as area fraction
            -Platy morphology in as-cast/low temperature heat treatments
            -Rounding-off at ≥950°C
            -Platy morphology detrimental to properties (corrosion & mechanical)
            -Near rounded/hexagonal forms preferred

(e) Grain boundary carbide $M_{23}C_6$:

        -Adversely affects corrosion resistance and deformation behaviour

(f) M_7C_3 & M_5C_2:

        -M_7C_3 present in the from of MC and also as eutectic carbide (eutectic form not preferred)

        -M_5C_2 present as MC and part of DC

(7) Structure-property correlations (Models):

(a) Heat treating temperature, time and hardness

(b) Weight gain as a function of temperature

(c) A correlation between corrosion rate and microstructure denoting the effect of MC & DC

(d) Interrelating corrosion & deformation behaviour
